Archiv für Anatomie und Physiologie (HIS, BRAUNE, und DUBOIS-REYMOND) Anatomische Abtheilung, Heft i. und ii. Leipsig. 1883.—This number of the journal contains papers chiefly devoted to development. The following is a list:—1. H. Strahl, Beiträge zur Entwicklung der Reptilien, with one plate. 2. Graf. Ferdinand Spee, Beiträge zur Entwicklungsgeschichte der früheren Stadien des Meerschweinchens bis zur vollendung der Keimblau. 3. V. Hensen, Ein frühes Stadium des im Uterus des Meerschweinchens festgewachsene Eies, with a plate. 4. A paper by the same author, entitled Bemerkungen betreffend die Mittheilungen von Selenka und Kupffer über die Entwicklung der Mause. 5. Wilhelm Roux, Beiträge zur Morphologie der functionellen Anpassung, with a plate. This article deals with the structure of a highly differentiated connective-tissue organ of the tail fin of the dolphin. 6. Wilhelm His, Ueber das Auftreten der weissen Substanz und der Wurzelfasern am Rückenmark menschlichen Embryonen, with a plate. And lastly, Jacob Heiberg, Ueber die Lehre vom Drucke der Bandscheiben des Kniegelenkes auf das untere Femurende, with a plate.

Archives de Physiologie. (MM. BROWN-SÉQUARD, CHARCOT, et VULPIAN.) No. 2, Fig. 15. 1883.—This part contains the following papers: 1. De la Neurologie, par M. L. Ranvier, with a plate. 2. Sur le Cylindrome (Epitheliome Alvéolaire avec Envahissement Myxomateux), par M. L. Malassez, with a plate. 3. Contribution à l'étude des Alterations Morphologiques des Globules Rouges, par M. G. Hayem. 4. De l'Ostéo-périostite Tuberculeuse Chronique ou Carie des Os, par MM. P. L. Kiéner et A. Poulet, with a plate. 5. Etude sur les Abscess Aréolaires du Foie, par M. A. Chauffard, with a plate.

Medical Annotations.

"Ne quid nimis."

CHLOROSIS AND PYREXIA.

ALTHOUGH much irregular fever has been detected in cases of so-called progressive or pernicious anæmia, the temperature of the ordinary cases of chlorosis met with in young women is usually believed to be normal. This belief has been contested by M. Mollière, in a paper contributed to a recent number of the *Lyon Médical*. His observations were made on eight young women, who presented no other signs of disease beyond the anæmia for which they were under treatment. The temperature was taken every morning and evening in the rectum, over a period varying from two to fifty days, and was found to oscillate between 101.8° F. and 102.8°. The amount of urea eliminated per diem was estimated, and found to be normal. Mollière suggests that the increased heat may be explained by the hypothesis of a com-

bustion the products of which are not so easily recognized as urea. Sulphate of quinine was given as an antipyretic, with the effect of reducing the temperature temporarily. This effect, if constant, would, according to Mollière, definitely establish the existence of abnormal body heat in chlorosis.

CURIOUS PARASITE.

At the last meeting of the Linnean Society Dr. Cobbold described a worm which he called *Simondsia paradoxa*. It is a nematode, the male living free in the stomach of the hog, whilst the female is lodged in cysts within the walls of the stomach. Although discovered thirty years ago by Professor Simonds, the worm has never been properly examined. The strange thing is that the female carries outside its body a large rosette-shaped organ. This the author of the paper considers to be the uterus, and compares it to the generative apparatus of *Spharularia bombi*. If Schneider's view be correct the prolapsed uterus of the nematode of the humble bee is nearly thirty thousand times larger than the maternal worm. The latter is a mere appendage, and was regarded by Sir John Lubbock as the male. Dr. Cobbold thinks that the branched rosette of *Simondsia* is homologous with the overgrown prolapsed uterus of *Spharularia bombi*.

THE RESPIRATORY CENTRE.

In a communication to the Société de Biologie, M. Laborde stated that he had repeated the experiment of puncture of the apex of the calamus by means of a very delicate method. Superficial irritation of this point with a needle leads in two or three minutes to arrest of respiration, the heart continuing to beat. He does not agree with the majority of writers that this effect is due to reflex action, but holds that it is direct irritation. Promising further proofs, he contented himself on that occasion with stating that division of the *crura cerebri* and of the *pneumogastric* nerves in no wise hindered the superficial puncture of the apex of the calamus from producing arrest of respiration, showing that the assumed intervention of the *vagi* or of the *cerebrum* was not necessary to the effect. Prof. Brown-Séquard, in speaking of this paper, said that in 1858 he showed that the "*noeud vital*" had not the importance attributed to it by *Fleurens*. His own experiments, extending over twenty-five years, pointed to the localization of the respiratory centre in the grey matter at the apex of the calamus. At the same time the most potent region governing respiration was to be found at the root of the spinal accessory nerve, although the respiratory centre extends over a considerable part of the cervical cord.

LAPAROTOMY FOR LARGE OMENTAL TUMOUR.

ABDOMINAL section was performed a short time ago at the Children's Hospital, Dublin, by Mr. Lambert H. Ormsby, Surgeon to the Meath Hospital. The patient an unmarried female, aged twenty-six, was admitted suffering from a large abdominal tumour of six years' standing. She had never been tapped. Mr. Ormsby operated under the antiseptic spray by the usual median incision as for ovariectomy. When the abdominal cavity was opened, an enormous quantity of ascitic fluid escaped, and the tumour came into view. It was multilocular, and contained some thick fluid, but made up for the most part of brain-like semi-solid matter. The growth was not attached to the ovary or uterus, but appeared to spring from the great omentum. The pedicle was

tied with two stout catgut ligatures, and cut off short. No cautery was used to the pedicle. The abdominal incision was brought together with catgut and silk worm gut sutures, and dressed with the antiseptic gauze. The tumour together with the fluid removed weighed 75 lb. The patient has progressed most favorably since the operation.

REPORT OF THE CITY ANALYST.

DR. SEDGWICK SAUNDERS reports that during last year 197 analyses were made, comprising milk, 95; butter, 2; disinfecting powders, 20; tea, 4; sugar, 10; whisky, 1; rum, 6; pepper, 5; and water, 54. Of milk, 54 samples were adulterated, the average amount of added water being 8.7 per cent. Both samples of butter were genuine. In the disinfecting powders the active principle in all was from 25 to 50 per cent. less than represented by the seller. The four samples of tea were pure microscopically, but of inferior quality chemically. The sugars were free from mineral adulteration, but all contained filaments of fungi, and two samples animal parasites. The samples of pepper were all dirty and sandy from careless packing and grinding. The water-supply had maintained its excellent character. No prosecutions had been instituted during the year, on account, he says, of the difficulty of obtaining convictions, and also on account of the great leniency shown by the magistrates in awarding punishment to proved offenders. Dr. Saunders expresses his regret that the officially appointed referees and censors in the Government department of chemistry at Somerset House had not seen fit to publish standards of purity both for the guidance of the analyst and to assist the magistrates in arriving at a just conclusion as to the extent any admixture of foreign substances in either food or drugs should be attributed to accidental and unavoidable circumstances rather than to fraudulent intention.

A GREEN CANCER OF THE CHOROID.

To most minds mere color is a very powerful means of arresting the attention; at all events, momentarily. The medical mind is peculiarly affected by the sight of pathological objects having an unusual color. Though there is hardly any color which has not been seen in the products of the human economy, yet the presence of a green tint in an extraordinary situation is sufficient to set the pathologist on the search after its nature, which, despite his efforts, frequently remains obscure. Dr. Emil Bock recounts in *Virchow's Archiv* the case of a tumour of the choroid which contained biliverdin. The growth was found in a man, aged forty years, who was the subject of cancer of the liver; presumably secondary foci were detected in many parts of the body: arachnoid, lungs, and subcutaneous tissues. A plate is given illustrating the characters of the ocular growth, which was composed of polygonal cells with large round nuclei, the streaks and dots of biliverdin pigment being richly scattered in an intercellular situation.

CRUELTY TO PIGEONS.

SHOOTING of tame pigeons is bad enough under the least atrocious of conditions, but when to make the birds lively men stick pins into their tails, and blind them with some torturing agent so that they may fly wildly when scared from the trap, "cruelty" is a very mild word to employ in the designation of what "Society" perversely calls sport. There is, happily, a hope that, owing to the intervention of the Princess of Wales, tame-pigeon-shooting may soon be regarded as no

longer a fashionable amusement. When this stage in the process of reform is reached, there will still remain the vulgar pastime in which unfashionable persons will doubtless continue to join. If the Legislature were not preoccupied, a short Act of Parliament might well be passed to make the shooting of tame pigeons, or any other birds let loose from traps, illegal. We have put down cock-fighting, although the cock undoubtedly gratified its natural instinct in the sport. Even the pugnacious rat is protected; but the poor defenceless pigeon and equally defenceless deer may be mangled and worried for the pleasure of benevolent men with entire impunity. When will the canting spirit of this sentimental age begin to give proof of a little consistency and common sense? The scientist must not inflict pain, even to elicit ways of cure from nature; but the bitterest agony may be ruthlessly inflicted on dumb animals so that it be done under the guise of "sport."

ACUTE YELLOW ATROPHY OF THE LIVER.

ACUTE yellow atrophy is still a mysterious disease whether we regard its etiology or the nature of the morbid process. Microscopical investigations have revealed changes which may be arranged under three headings. First, swelling and destruction of the polyhedral cells; secondly, an infiltration, chiefly of small cells, in the interlobular regions, which was first described by Winiwarter; and, finally, an apparently new formation of the smallest bileducts in direct continuity with the pre-existing biliary passages. The latest observations of Haren Noman (in Virchow's *Archiv*) corroborate to a large extent the researches of Winiwarter, but the small-celled infiltration was not found to extend into the lobules. He describes patches of yellow and red color which may be seen with the naked eye, and sometimes adjoin one another. The yellow areas, microscopically, exhibit swollen and granular hepatic cells, some containing small fat globules; the intervening connective tissue is much thickened and sparsely strewn with refracting nuclei and fine dots, which stain well with dyes. The red areas have a structure something like that of a cavernous angioma, a network with irregular meshes filled with red discs and a few leucocytes. It seems that a special examination for bacteria was not made, although gentian violet and other powerful staining fluids were employed. Having regard to the mysterious nature of this usually rapid disease, it is desirable that the possibility of the presence of specific organisms should be borne in mind by any future investigator.

PROFESSOR BLACKIE ON LUXURIOUS DINNERS.

At the close of a recent lecture on "Luxury," Professor Blackie, who is always amusing and generally sensible in his satire, indulged in his peculiar vein of acrid humor anent luxurious dinners. The professor, who is not an austere ascetic, informed his audience that it was his wont to say "no" to every second dish. This seems exemplary, and fits in admirably with the orator's dictum "that modern dinners are an admirable call to self-denial." We quite agree in the opinion that dinners are apt to be too luxurious, but we also agree that "a dinner carried on for two hours is much better for the digestive faculties than a badly cooked steak to be eaten all at once." Even though it be true that a dinner *à la mode* in this last quarter of the nineteenth century is a "magnificent spread of animalism," it is not necessary to partake of all that is offered. Nor, indeed, is it expected that we should do so. A well-assorted

dinner is an opportunity for dining. Each guest can and should choose the viands most to his taste and least likely to disagree with him. There ought always to be several, if not many, alternative courses, so that the different tastes of the invited may be satisfied. There is too much talk nowadays of "little dinners." A "little" dinner is all very well when two or three intimate friends are dining together, and the caterer happens to know that the party are so far agreed as to be all easily satisfied. When the number of guests exceeds two, or at most three, a "little dinner"—that is, a dinner comprising only a very limited number of courses—is almost sure to leave one or more of the party without enough to his liking. We ought to be more eclectic than we are in the matter of feeding. A varied and tasty diet is necessary for our modern life. Eating does not consist in packing a sufficient quantity of food into the organs of digestion. Man is more a creature of food than a creature of circumstances, and he who would live well in a mental, moral, and physical sense, should feed well—that is, in the way that best suits his organic requirements, and, not less, his taste and mood.

DIPHTHERIA AND NEPHRITIS.

WE are still in want of observations which shall throw light on the nature of the renal changes associated with diphtheria. Our readers have been kept *au courant* with the latest writings on the subject, and are therefore fully acquainted with the doctrine of the infective nature of the nephritic alteration. It is philosophical to bear in mind that albuminuria, so often attendant on cases of diphtheria, may not necessarily be due to actual disease of the kidneys; the manifold antecedents or causes of albuminuria may still come into play, even although the body be the subject of diphtheria. The presence of one cause, however probable its action may be, does not preclude the possibility of a less striking factor being the real agent in any particular instance. We are led to make the foregoing remarks, because Dr. Fürbringer, in Virchow's *Archiv* for March, has been unable to detect the micrococci which other observers have demonstrated in the urine and kidneys of cases of diphtheria. We are far from asserting a full belief in the view that diphtheritic nephritis is even generally a bacterial disease; on the contrary, the notion that the primary diphtheritic disease is due to micrococci requires more convincing evidence than has at present been adduced. Dr. Fürbringer has investigated the clinical history and morbid anatomy of diphtheritic nephritis with much industry. He comes to the conclusion that the renal changes may conveniently be arranged under three divisions, according to the degree of anatomical change. The earlier stages are characterized by comparatively slight changes in the epithelium of the cortical region, not unlike "cloudy swelling," next the cellular degeneration becomes more decided and more widely spread; and there are some alterations in the interstitial tissues, but no vascular lesions. The final degree is comparable with that of the intensely congested kidneys sometimes seen in connection with nephritis after scarlet fever.

TUBERCLE BACILLI IN URINE.

WE lately referred to the observations of Rosenstein on the occurrence of tubercle bacilli in the urine in a case of supposed tubercular disease of the urinary organs. His communication has evoked from Dr. Babesiu, of Pesth, a reference to a previous observation of still greater significance.

On Jan 26th this physician demonstrated to the Anatomical Society of Paris bacilli from the urine of three patients, in two of whom the disease was subsequently ascertained by post-mortem examination, and was found to be tubercular kidney disease with ulceration of the pelvis of the kidney; and in one there was also tubercular ulceration of the bladder. In searching for the bacilli he followed in part the methods of Ehrlich and Koch, in part anilin fuchsin, or anilin methyl violet, and stained the bacilli for from twelve to thirty-six hours. Instead of nitric acid, he several times employed with advantage strong acetic acid. In one case the bacilli were found within pus cells and in large round cells, but not within the epithelial cells of the bladder or pelvis of the kidney. In the case in which tubercular ulcers of the bladder coexisted with tubercular disease of the kidney, the microscopical examination showed that the bacilli were located chiefly in cells which probably belonged to the endothelium of the most superficial lymphatic spaces. A further stage of the morbid process consisted in the production of a follicular reticular tissue, in the swollen round cells of which the bacilli were collected, so that these spots were visible to the naked eye as reddish points in specimens treated by the modification of Ehrlich's method. In the centre of these spots were giant cells containing bacilli. In the larger ulcers the bacilli were less distinct in the caseous material than at the edge in the miliary tubercles, and they were frequently seen in the granulation tissue immediately beneath the caseous layer. In the tuberculous masses in the kidney the bacilli were found chiefly at the margin of the destroyed tissue, in the vicinity of the granulation tissue, and especially in giant cells, although there was no aggregation in foci, such as was seen in the mucous membrane. In the necrotic cheesy masses none could be discovered, or in those giant cells which had manifestly arisen from epithelial structures. These observations certainly go far to establish the diagnostic value of the bacillus in tubercular affections of the urinary organs.

ERGOT OF RYE IN LOCOMOTOR ATAXY.

M. GRASSET, of Montpellier, has lately drawn attention to the fact that ergot of rye administered in tabes dorsalis may do more harm than good. He gives brief notes (*Progrès Médical*, 1883, No. 11) of the case of a man who was the subject of this disease, and who had become much better when he was prescribed ergot of rye in increasing doses from twenty-five centigrammes up to one gramme per day. On the second day of taking the maximum dose he became generally paralyzed; the arms, which had never been attacked before, now being involved. Sensation was also much diminished. The ergot was at once left off, and he gradually lost the paralysis; but the ataxic symptoms in the lower limbs persisted. M. Grasset points out that the involvement of the posterior columns is not generally regarded as a symptom of ergotism; but Nothnagel and Rossbach mention anaesthesia and motor incoördination among the symptoms induced by moderately toxic doses of ergot of rye or sclerotic acid in animals, large doses producing a state of general paralysis; and he refers particularly to the account given by Tuczek lately on the changes in the spinal cord, particularly in the posterior columns in ergotism. Tuczek's observations were made on eighteen out of twenty-four patients admitted into the Marburg Asylum with mental disease among 500 who were attacked with ergotism. Four patients died, and examination of their spinal cords threw light upon the spinal symptoms exhibited by all the cases. These

symptoms consisted in abolition of the knee-jerk (which returned in those who recovered), paræsthesia, lightning pains, anaesthesia, analgesia, ataxy, etc. The lesions found consisted in sclerosis of the posterior columns throughout the cord, in two cases extending to the medulla. The change was symmetrical, and limited to the columns of Burdach. Tuczek endeavored to reproduce these effects in animals by the injection of ergot of rye, but failed. He found, however, that in the rabbit hypodermic injection of sclerotic acid in doses of three to four grammes produced actual ataxy. From this, and from the case he relates, Grasset thinks that ergot of rye should be most carefully administered in locomotor ataxy. In a foot note appended to the paper M. de Bourneville states that Professor Charcot very often prescribes ergot of rye in tabes, and has never observed any ill-result from it. He gives it in daily doses of twenty-five to thirty centigrammes, but not continuously, the drug being taken for four days and discontinued for two, and so on.

MILK IN VILLAGES.

It has been said for centuries that the nearer the church the worse the people, and in this day it may be remarked with truth the nearer the dairy the less the milk. At the present time many complaints are being made and much wonder expressed that the rural population is everywhere diminishing in this country. This is no doubt true, and the reasons are not far to seek. One is undoubtedly the want of consideration shown to the poor by employers of labor in villages, both squires and farmers. In the agricultural districts it is, as a rule, impossible for the poor to obtain milk for love or money, and in consequence the children sicken and die. The reason is that the sale of milk to the villages in small quantities gives trouble, and is not so profitable as giving it to the swine. Hence, none of the milk finds its way into the cottage, but all is given to the calves and pigs. An example of how cruelly this action of the landlords and farmers tortures the poor has recently come to light. In a small village, in three weeks, out of a population of 100 souls, three children are reported to have died from want of that nourishment which good milk can alone supply. In one of these cases the parents resided under the same roof that covered the squire's dairy, wherein was stored the milk of a large herd of cows. Not one drop was, however, allowed to be given to the suffering little one, nor in this village are the poor afforded facilities to obtain milk. In consequence the diet of these babies was found to consist of corn-flour, bread and water, and death soon terminated their sufferings. No wonder the population in villages is decreasing. It would be a great gain if the clergy in each parish were to arrange to supply milk from the school or some other centre. The present state of things is a disgrace to our common humanity, and a remedy must speedily be found for it.

THE LAW OF CONTRACTION IN MUSCLE.

In a paper published in the *Archiv für Physiologie* of Dubois-Reymond for 1882, by Ernest v. Fleischel, this observer endeavors to show that in the case of the nerve supplying the gastrocnemius, of the frog, the whole nerve is divisible into three sections, the first of which extends from the muscle to the origin of the branches for the thigh, and consequently to the exit of the sciatic from the pelvis; the second segment extends from this point to the division into a motor and sensory root, and consequently to the intervertebral ganglion; and the third segment extends from this ganglion to

the central extremity of the nerve. Each of these three segments consists of two parts, an upper and a lower "pole," with an intervening equator, the latter being situated below the middle point of the segment in most cases. In the upper pole of each segment the nerve is most sensitive to descending currents, in each lower pole to ascending currents, whilst at the equator the excitability is the same for both. If the continuity of a nerve be interrupted by ligature or section, the equator of this segment gradually descends towards the muscle. The points where the segments are in apposition, which he terms "consequent" or "consecutive points" (Folgepunkte), as well as the point situated just above the entrance of the nerve into the muscle, are points of small absolute sensibility. Fleischel decides against the "Zuckungsgesetz," or law of contraction, of Stricker.

PRIMARY ACUTE MILIARY CARCINOSIS.

A SUFFICIENTLY searching scepticism is always necessary in medical science, and it is at no time more needed than when an attempt is made to add a new name to medical nomenclature. There are no *a priori* reasons why carcinomatous nodules should not crop up in various parts of the body under the influence of mere general conditions. It is conceivable that certain of the tissues in certain individuals may as naturally become carcinomatous as those of others fibroid, external agencies apparently having but little influence in the matter. Modern pathology, however, gives an important place to the doctrine of infection, and in the presence of the actual the mind instinctively turns from the merely conceivable. There can be no doubt that the majority of physicians would be extremely careful to exhaust every source of infection before coming to the conclusion, in any particular case of cancerous affection of the serous cavities, and they had to deal with a primary carcinosis of those structures. MM. Raymond and Brodeur diligently but unsuccessfully searched for the primary disease in the case which they have reported in *La France Médicale*. The observation was made on a man, aged seventy-six, who showed during life symptoms similar to those induced by pulmonary tuberculosis; palpation of the swollen abdomen, moreover, is said to have revealed the existence of disseminated hard nodules, varying in size from a pea to a bean, apparently separated from the observer's hands only by the thickness of the abdominal wall; there were, in addition, periodic febrile attacks simulating ague. To inspection with the naked eye, tubercles and nodules of carcinoma are sometimes wonderfully similar. The microscopical characters described in the above case were those of genuine carcinoma, growths from the pericardium, pleura, and peritoneum having essentially the same structure. There was a tumour in the liver which the authors assured themselves was nothing more than a cavernous angioma. Charcot has recorded two similar cases also occurring in old age, and, like the present one, having no hereditary taint. If the observations be true, we must recognize the existence of the disease which is called "primary acute miliary carcinosis."

THE "NEW CODE" OF ETHICS IN AMERICA.

OUR readers will remember that at its annual meeting last summer, the American Medical Association expressed in no ambiguous fashion its dissent from the course taken by the New York State Medical Society in so altering its code of ethics as to allow its members to meet on equal professional terms any legally qualified practitioner, be he

homœopath or any other of the large army of "irregulars." The conflict has been waging ever since. Other State Societies have stood to their colors, and asserted that their members should be men of honor, worthy of the traditions of their profession, and not mere money-makers. The State Society of New York recently met at Albany, and after a warm discussion, in which we are glad to see Dr. Austin Flint made a powerful speech in favor of what is by most men considered the more honorable course, a vote was taken, and the new code was affirmed by six votes. We can but lament this result. The question is evidently exciting strong feeling on the other side of the Atlantic. The victorious majority threaten to proceed even further, and to abolish all restrictions in professional intercourse, while the minority, numbering among it the most trusted leaders of the profession, feeling that their cause are just, are quite unable to bow to the decision of the majority. Unfortunately it is boldly stated that the leaders of the advocates of the new code are entirely "specialists," and it is obvious that such a change will be likely to benefit such men pecuniarily. We cannot believe that this vote at Albany fairly expresses the opinion of the profession in the State of New York, and we trust that very soon wiser counsels will prevail and this false step will be retraced.

Correspondence.

"Audi alteram partem."

THE LOCAL TREATMENT OF ERYSIPELAS WITH WHITE-LEAD PAINT.

To the Editor of THE LANCET.

SIR—I send you the particulars of two cases of erysipelas which have occurred in the wards of our infirmary during the last few days, and in which the treatment by white-lead paint, recommended by Mr. Barwell has been adopted with satisfactory results.

CASE 1.—Thomas C—, aged sixty-three, with large chronic ulcers encircling his right leg, complained to me on my morning round, on March 16th, of pain in the leg and of not feeling so well. On examination I found the ulcers had stopped discharging, and the whole foot and leg, to about three inches below the patella, were covered with an erysipelatous blush; his tongue was furred, bowels constipated, pulse 100, temperature 100·8°. He had had no vomiting, but a certain amount of shivering. The limb was painted all over, ulcers excepted, with white-lead paint. Within twenty minutes he said he had lost all pain and feeling of heat in the limb; and his temperature, taken carefully that night, was 98·4°. On March 18th the paint was chipping off, and the skin beneath was the normal color.

CASE 2 gives a still more striking result. This was a boy, aged seventeen, who has been in the hospital three months, with a sinus in his leg, leading down to diseased bone, and whose ordinary temperature during the last few weeks had been 99°. On the morning of March 18th the leg and foot presented a well-marked erysipelatous redness. He had had rigors and vomiting. His temperature was 103·8°; pulse 110; bowels constipated. His leg was painted on the afternoon of the same day; in the evening he was perfectly easy. Temperature 102°, and on the following morning 99°. He said he felt quite as well as

usual. He has had no relapse up to the time of writing.

The only internal treatment in both cases was at the time of painting ten grains of calomel and colocyath pill.

I remain, Sir, yours truly,

E. COLBY SHARPIN,
Acting House-Surgeon.

Bedford General Infirmary, March 26th, 1883.

APHASIA.

To the Editor of THE LANCET.

SIR—Cases of aphasia uncomplicated with hemiplegia or loss of power or sensation in any part of the body are so rare that I think a few particulars regarding a patient thus affected may interest some of your readers. At a meeting of the Clinical Society of London, November 24th, 1871 (THE LANCET), Dr. Moxon is reported to have said "that aphasia meant that state in which words are forgotten and cannot be used when repeated to them." Very concisely this expresses the condition of my patients. The latter part of the definition holds good if a little time elapses between the moment at which a noun substantive is given and the time at which it is again asked to be repeated. If my patient is told the name of a neighboring farmer well known to him he readily forgets it. Nevertheless, this man knows the names of many things; watch, knife, purse, etc.; moreover, he can read with ease, and can write anything if the matter to be written is placed before him.

The history of the case is briefly as follows: On the 3rd of January, about 6 A.M., my patient, a strong and healthy farmer, before leaving his bed conversed about his plans for the day as freely and intelligently as formerly, and apparently, so far as his wife could judge, enjoyed perfect health. His wife informed me that she noticed nothing unusual about him until he allowed the utensil to fall on the floor on first getting out of bed. He again lay down and seemed to be a little "wrong with his words." I saw him at 8 A.M. and found him aphasic. A few questions elicited the facts that on the night previous he had two glasses of whisky and water, that he felt quite well, but that his bowels had not moved for two days. The heart sounds were normal, and the urine contained no albumen. I have no suspicion whatever of syphilis, and he never suffered from rheumatism. He is withal a temperate man in the prime of life. Twelve days after seizure I find little or no change in his condition beyond a more intelligent and lively expression of countenance. He enjoys the company of his children and their conversation, and heartily laughs at his own condition. On attempting to join in the conversation he breaks down and fails to command the words necessary to convey his ideas. Clearly enough the thoughts or ideas which lead to verbal expression are present with him, but he cannot give utterance to them. I think I am justified in calling this case an uncomplicated one. True, he committed a mistake which under ordinary circumstances would not have occurred, but he could always walk steadily and firmly grasp with his right hand.

The treatment, I may add, consisted in free purgation, the liberal application of leeches to the left forehead, and the internal use of iodide of potassium. Dr. Glover described in THE LANCET, in 1872, a similar case in a man aged sixty-three, and as in his case, so in this, there is no symptom which indicates any affection of the left hemisphere more than the right.

I am, Sir, yours truly,

R. McK.

Jan. 15th, 1884.

"AN INTERESTING QUESTION."

To the Editor of THE LANCET.

SIR—With reference to Dr. Cory's query, I should say the first child of the second marriage would be more of a mulatto than white; the subsequent children would approach nearer to the white type with each successive pregnancy. In the case mentioned of the mare and quagga, the first foal got by the pony stallion would be more of the quagga than the last. This is, I believe, in accordance with a rule of nature observed amongst animals that the impression of the male influences the offspring of the female by another male. As an illustration, I will mention a case in point that came under my own observation. A white fantail pigeon mated with a female blue rock; the result was half fantails of mixed color. The male bird getting killed, the rock paired with a common white pigeon. The first progeny of this union were half fans, or very nearly so; while the subsequent young were still "fanned," but to a smaller degree, the last brood being considerably less so than the first.

I am, Sir, yours truly,

J. D. MILLER, M.D.

Notting-hill, March 12th, 1883.

To the Editor of THE LANCET.

SIR—In reply to the latter part of Dr. F. C. Cory's letter on the above subject, I beg to inform him that the experiment was not tried in the "Zoo," but in the park of Lord Moreton, who, having a pure bred Arabian mare, introduced to her notice a handsome male quagga, by whom she was covered, after which the quagga was removed from her sight. In due time she brought forth a foal, very like herself; but being subsequently covered by a handsome black stallion, the offspring was more like the quagga, and each subsequent foal by the black horse being more and more like her first love, as Dr. Cory and your other readers may see by a visit to the College of Surgeons, where some well-executed paintings demonstrate this fact. I think his lordship published an account of this interesting matter in the Philosophical Transactions.

I am, Sir, yours, etc., T. M. STONE.

King's-road, Wimbledon, March 12th, 1883.

FOOT-AND-MOUTH DISEASE AND THE LYING-IN WOMAN.

To the Editor of THE LANCET.

SIR—I have recently seen in consultation a case of fatal metria. On inquiry, I found that the patient had been supplied with milk from a farm where foot and mouth disease was widely prevalent. All other causes of zymotic or septic poisoning were apparently capable of being eliminated; and though there was fetid lochial discharge, a careful investigation of the uterine cavity discovered nothing, and repeated washings of its interior produced no favorable results on the temperature, so that one may set aside what Duncan terms sapræmia. The sanitary surroundings of the house were also excellent.

I should like very much to know whether any of your readers have met with or suspected foot-and-mouth disease as a cause of material blood-poisoning. There is little doubt that everyone of the human infectious diseases may give rise to the symptoms of the so-called puerperal fever in the lying-in woman; and, reasoning by analogy, one would expect the same from the bovine affection. Yet surely in that case there should always be numerous recorded instances. The lady's friends

naturally expect a positive answer to the question, May the milk of cows thus affected produce these results? I can only answer provisionally, that I think it entirely probable. In that district, several miles from Manchester, where the case occurred, there is a wide prevalence of foot-and-mouth disease, and with the greatest care on the part of the farmers there would still be a source of extreme danger to the lying-in woman there.

As the matter now stands I would certainly advise that no milk should be used by the lying-in woman in such a district, certainly none that had not been subjected to boiling.

If any corroborative cases have been published I have missed or overlooked them.

I am, Sir, yours, etc.,

J. THORBURN, M.D.,

Professor of Obst. Med., Victoria University.

Manchester, March 12th, 1883.

TRANSCIENCE OF NERVE-FORCE.

To the Editor of THE LANCET.

SIR—I am very anxious to know if it is altogether a popular error that in the case of two people—say sisters, servants, or married people—sleeping constantly in the same bed, one can, and does, derive nerve-force, or its congenor, electricity, from the other? I am, Sir, faithfully yours,

DELTA.

April 2nd, 1883.

. We do not know of any evidence tending to demonstrate such an action as that to which our correspondent refers, nor do we think it at all likely that any influence of the kind exists; but "there are more things in heaven and earth than are dreamt of in our philosophy."—ED. L.

GONORRHOEA TREATED BY BELLADONNA.

To the Editor of THE LANCET.

SIR—Having successfully treated a few cases of gonorrhoea by smearing the penis with ointment of belladonna and enveloping it in a cloth smeared with the same, I beg to suggest the treatment to those who have opportunities of testing its efficacy. The cases in which it was tried were mild; no injections were used nor internal medicines employed, and the cure was complete in a week.

I am, Sir, your obedient servant,

J. NUMA RAT, M.R.C.S.E.

Venezuela, Tucacas, March 5th, 1883.

"CASTOR OIL AND GLYCERINE."

To the Editor of THE LANCET.

SIR—In a recent issue of THE LANCET I see a communication from Mr. William Soper, concerning his method of administering castor oil in small doses along with glycerine. This method is not altogether new, for I have frequently dispensed castor oil in combination with glycerine as a mild laxative for ladies in pregnancy and delicate children, for which purposes it is well suited, as also for mild cases of habitual constipation. A mixture, which is of an agreeable flavor, and in which the nauseous smell of the oil is efficiently disguised, can be made thus:—R Ol. ricini, 3i; glycerini, 3i; tr. aurantii, 20 minims; tr. senegae, 5 minims; aquae cinnam. ad 5jss. This forms a beautiful emulsion, is easily taken, even by children, and if administered at bedtime will produce

a gentle motion the following morning. In cases of habitual constipation, when this mixture is repeated for three or four nights it brings about a regular morning motion. The tincture of senega is used to emulsify the oil, and as the quantity employed is small, its use cannot be objectionable from a therapeutic point of view.

I am, Sir, yours respectfully,

GEORGE R. YOUNG, M.P.S.I.

Belfast Royal Hospital, Feb. 10th, 1883.

News Items, Medical Facts, &c.

DR. RICHARD MCSHERRY, Prof. of Principles and Practice of Medicine, University of Maryland, Baltimore, Md., says: "I have used the preparation known as 'Iodia,' prepared by Messrs. Battle & Co., of St. Louis, in my practice, and have found it a very satisfactory agent in cases for which it is deemed most appropriate."

MURDOCK'S LIQUID FOOD.—This American preparation is described as "an extract of beef, mutton, and fruits, containing corpuscles, and 12½ per cent. of soluble albumen." The solution gives the blood spectrum very strongly, and contains so much albumen as to become almost solid with dilute nitric acid. Of course it is an exceedingly powerful and easily digestible form of food. It is calculated to be of the utmost use in medical practice, and although the flavor is not very pleasant, it is not absolutely disagreeable, and may no doubt be modified by salt and spices. Among other applications, the use of the liquid food as an enema will strike everyone.

REFERRING to a case recently decided in France, in which the accused, who had applied compounds made by a quack, and of the composition of which he was ignorant, was, although a regular physician, fined and imprisoned for the illegal practice of medicine, an American medical contemporary says that the existence of this French law is both a standing reproach and a good example to American medical legislators, and advocates the passing of a Bill couched in the following terms:—"Any practitioner of medicine, claiming to be a regular physician, who shall prescribe secret remedies, the composition of which is unknown to him, shall be deemed guilty of a misdemeanor, punishable by fine or imprisonment, or both.

THE INFLUENCE OF ELECTRIC LIGHT ON THE EYE-SIGHT.—The above subject has been occupying attention in one of the district medical societies at Vienna. Dr. Kraus, at a recent meeting, brought forward the question whether the introduction of electric light into schools, dwelling houses and public buildings was liable to any objections from a sanitary point of view. During the discussion which ensued, Professor Mauthner gave an interesting summary of the subject, from which it would seem that there exists but little practical evidence on the question at issue. The press has expressed a hope that the suggestion made in Vienna will be taken up in other European capitals, with a view of the matter being inquired into by medical societies. The statements made on the occasion referred to tended to prove that theoretically there is no objection to be urged by the profession against the electric light, except when in such an intermittent form as to cause discomfort to those in the vicinity of the lamps.

Croonian Lectures

ON

MODERN THEORIES AND TREATMENT OF PHTHISIS.

Delivered at the Royal College of Physicians, London,

By JAMES EDWARD POLLOCK, M.D.,

Consulting Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

LECTURE II.—PART I.

MR. PRESIDENT AND GENTLEMEN—In my former lecture I had to ask your indulgence while we considered in review the several theories regarding the nature of phthisis which prevailed up to a quite recent period. The necessity for this retrospect will, I hope, be apparent as we proceed to an analysis of the present pathology. Nor, as I trust, will it prove impossible to reconcile the various views of many observers, who saw only by the light of existing pathology, and could scarcely be expected to prophecy of the future. In so far as they were skilled observers and faithful recorders of what they saw, their records are invaluable and necessary portions of our knowledge; no additions which can be made, and no theories which could be started, can do away with the foundation of facts thus established. The reasoning from such may vary, and prove to be true or unstable; but the record is imperishable, and has become the property of all succeeding generations of pathologists. The great danger has been at all times a too exclusive method of arguing from a few facts, and more injury than can be estimated has resulted to the study of phthisis from regarding it as a special affection, and so separating it from the great mass of general pathology. It is possible that many, if not all, diseases are specific in one sense—that is, they may have a peculiar and individual cause, and an undeviating course in dependence on it, and to this view the modern pathology undoubtedly tends; yet that any affection stands outside the general laws of diseased action and may be studied apart from others would be an error misleading in the study of that individual disease, and which must inevitably result in mistakes.

We have now arrived at the germ theory of phthisis, having examined those of the French and

German schools which preceded it, and, so far as we are able, the English mind on the subject; and as I hold it impossible to subject phthisis to an isolated examination, and to regard it as separated from general pathology, I shall take the liberty of examining briefly the whole theory of the induction of diseases from germs introduced from without, as well as the disorders resulting from their introduction into the economy of the living body, and the method of their multiplication in the system, with the symptoms thereby induced. We shall then examine the phenomena of phthisis from this point of view, comparing its symptoms with those of other affections which are recognized as due to a similar infecting cause.

In the outset, let us observe that the argument regarding the introduction of germs, parasites, or septicæmia into the living body implies a recognition of the localization of disease. None of the theorists argue that the whole system is at once infected. There is a given starting-point, be it the wound or inoculated spot, and even when the breathed air has introduced septic or specific germs into the blood by the lung, it must, and does, soon find a local centre in which it forms a nidus, and whence it spreads by some of the methods we shall consider. That each specific germ has a point of selection, or a locality, in which it can especially grow and multiply, is an observed and necessary part of the infection. Thus the typhoid germ selects the mucous glands of the intestines, and the poison of rabies the brain and nerve centres, probably the pons. From this consideration it is evident that there are structural or other peculiarities of certain localities in the body in which they differ from other parts. To carry this view higher, it may be almost considered that the proposition of Bichat is true, and that the various tissues are possessed of a particular life. The modern theory would seem to show that you can poison the individual life of certain tissues, as the nervous, or at least that certain infectants address themselves peculiarly to particular structures of the body, and there find a centre in which they flourish, and in which alone they can germinate and fructify. Bichat taught that the life of superior organisms, as man, is not due to the action of a unique central force, but to the ultimate result of the particular lives of the various tissues which enter into their composition. The organism of an animal he likened to a federal State, and the elementary cells to the citizens. Virchow, in his Cellular Pathology, especially studies to discover

the causes which interfere with the life of the ultimate tissues of the body, and he thought that a great number of the disease-producing causes are living beings, vegetable and animal, which live as parasites at the cost of the human organism. There is no doubt therefore that long before there was any discovery of infecting germs the pathological mind was being prepared for the new theory. It was no longer sufficient to recognize a blood-poison acting by indescribable means on the whole system, devitalizing and destroying it in totality, but it was seen that the death of particular parts of the system was possible, and that certain poisons addressed themselves to certain structures. This was proved to be true of chemicals introduced from without, as lead, which affected the muscles, or antimony, which is found in the solid viscera. It is but a step from this to recognize that certain germs manifest a selection for certain parts of the human body, and this was seen in the days before microscopes, in the known habitats of hydatids in the liver, lungs, and brain, in the lumbricus in the small intestine and the ascaris in the rectum. In 1835, Owen found the trichina, and Virchow somewhat later described the fever dependent on these parasites and their peculiar site in the muscles. There are, doubtless, other examples, but the foregoing will illustrate the fact that the localization both of certain poisons and of certain parasites was known. In 1836 Latour gave the name of *torula cerevisia* to the ferment which converts sugar into alcohol and carbonic acid. The vegetable nature of certain germs, and their power of indefinite multiplication, by assimilating to themselves all the materials of an organism to which they are exposed, till "the whole lump be leavened," must have struck many thoughtful observers. The experiments of Schwann at Berlin in 1837 proved that meat can be preserved from putrefaction by keeping it from the air or by subjecting the air to a high temperature, and upset the theory previously held that septic processes are due to oxygen. Thus we arrived at the fact that putrefaction is caused by organisms springing from germs in the air, and that heat can deprive these germs of their vitality. As the *torula* converts sugar, so germs convert albumen. In both instances the minuteness of the agent is remarkable. It was found that putrefying pus contains myriads of vibriones or jointed bodies which arose by a process of self-multiplication out of similar bodies by segmentation, or fissiparous generation. Pasteur's well-known experiments confirmed these results and largely extended them, and it was thus established that the atmosphere is filled with myriads of such germs, found indeed less abundantly on the tops of the Alps, or in equatorial parts, but literally everywhere. From hence has arisen the well-known methods of Professor Lister, who has applied the knowledge of these facts with such splendid results to operative surgery.

In 1866, Rindfleisch first noticed bacteria in the organs of those who died of traumatic infective disease, as pyæmia and puerperal fever in the form of pinhead deposits in the heart and muscles. Later on these become filled with a thin fluid pulp. These cavities contained vibriones, which afterwards penetrated between the fasciculi of the muscles, and then into the muscular fibre. They were found in the heart and kidney, and finally in the blood. The unhealthiness of a wound was found to be in direct proportion to the number of spheroid bacteria in its pus, and general infection was held to be due to bacteria in the blood. Further observations demonstrated the existence of micrococci in the bullæ of erysipelas, and in the lymphatics on the edge of the erysipelas. Bacteria were also found in the pus of phleg-

monous abscess, in its walls, and in diphtheria. In the latter diseases they penetrate deep layers of tissues and lymphatics. When traumatic infective diseases set in the discharges become putrid. Anthrax is remarkable for the uniform presence of bacteria. These were also found in scarlet fever, small-pox and typhus, as also in cholera. The two tests of microscopical examination and chemical reaction were applied by Koch to these parasites in septicæmia, and the diseases we have named, and a third and most important one, inoculation. In form the bacilli are found either as bacilli or micrococci, as chains of granules, or rods, or long oscillating threads. Koch thinks that a distinct bacteric form corresponds to pyæmia, septicæmia, erysipelas, gangrene, and spreading abscess; but Nægele says, "I have for ten years examined thousands of different forms of bacteria, and I have not yet seen any absolute necessity for dividing them even into two distinct species." It is certain, therefore, that a peculiar morphological form is common to several diseases, as pyæmia, diphtheria, small-pox, and cholera; yet even Koch is struck by the difficulty, and says that it is impossible that all these diseases can be produced by one parasite, and asks, although the bacteria appear the same, may there not be a difference, just as the sweet and bitter almond look alike, but have important chemical differences? Chemically it has been found that bacteria resist acids, alkalis, and ethers, but are demonstrable by their absorption of certain aniline dyes; and it is to this fact, as is well known, that we owe their recognition with certainty. It is possible to remove the albuminoid structures in which they are imbedded and leave the colored vegetable parasite.

The experiments by Davaine on inoculation of animals with putrid matters are well known, and the remarkable fact discovered that by transmitting the infection through a series of animals the germs are not exhausted, but multiplied, so that at last he succeeded in producing the characteristic effects by using the trillionth part of a drop of blood. He thus infected successively twenty-five animals. He used diverse fluids, from scarlet fever, puerperal fever, small-pox, typhus, and always found bacteria in the blood. He also produced diphtheria and erysipelas artificially in animals. He found (as did Koch) that bacilli grew into the vessels and entered the circulation through spaces in their walls. They penetrate the white corpuscles of the blood, the capillaries and large veins, and appear to have entered the system by the subcutaneous cellular tissue in the neighborhood of the spot inoculated. It is found that when the bacilli disappear the disease can no longer be produced by inoculation. The animals made use of in these experiments were rabbits and mice; but Koch distinctly states that the septicæmic bacillus cannot be inoculated on every animal, and often failed in mice. On the other hand death occurred in twenty-four hours after inoculation with the smallest drop of blood from anthrax, and the lungs, liver, spleen, and capillaries were found filled with bacilli. The well-known experiments of Pasteur and Klebs, which have been called the culture of germs, offer much evidence on the difficult and disputed question as to each disease in which bacilli are found having a separate parasite which is capable of identification. Taking a material presumed to contain an infective virus and others, they have by exposing it to certain conditions of temperature and free access of oxygen found one germ specially grow, and its infecting power increase more than the others. A preponderating development thus obtained in one germ is found to have stronger infecting powers than the others in the mass ex-

aminated. By successive experiments the one infecting germ is isolated. To this have been applied both the inoculation test described, and also the chemical. Thus it has been observed that the bacillus of anthrax does not color with fuchsin, while that of leprosy does. Crudele is of opinion (and no one has more thoroughly adopted the germ theory) that in the greater part of cases there is no proof of different kinds of bacilli except from pathological effect, and that we must obtain the morbid ferment isolated from every other substance with the greatest clinical care. He acknowledges that the entrance of septic ferments into the blood is not always followed by disease, and contends that for such production of morbid effects they should necessarily find a home in the body, and there grow and form a colony.

I have hitherto considered septicæmia and the opinions of experimenters on the so-called ferment and on the parasitic bacteria presumed to be the essential cause. But we are aware that many other diseases besides those named are referred to the same cause—namely, germs entering the system from without, and amongst these are found malarious fevers, and notably tubercle. Before proceeding to discuss the latter I would state in a condensed form the physiological and pathological reasons assigned by the eminent originators of the doctrine of germs both for and against the theory. Pasteur argues that all contagious endemic and epidemic diseases result from ferments. All infectious diseases are due to living beings capable of multiplying in the organism. He argues from the disproportion between the determining cause and the effect—the quantity of the poison introduced in relation to the gravity of the resulting disorder; and, secondly, from the reproduction of infecting material in the organism in enormous quantity.

Chemical ferments do not augment in quantity, although they produce changes in the composition of other substances. In living ferments they always go on increasing in proportion as the fermentative process advances; precisely what occurs in the specific agent of each infection during the course of the specific disease. The incubation period is remarkable. In chemical ferments we should see the specific action always show itself till it had met with all the material in the organism which it was capable of decomposing; but in animal ferment there is always an incubation found, more or less long, till the germs are evolved of all the living organisms which constitute the disease. It may be supposed that these remarks apply only to diseases of infection or contagion, like scarlet fever or erysipelas; but it will be seen that they are made with regard to the most chronic affections attributed to parasitic origin, as tubercular diseases and also to malaria and rabies. The duration of the incubation period varies according to the species of the infecting agent. It is short in the acute exanthemata, longer in others of milder course. Tuberculosis has a latency of twenty days, and rabies often a period of years. As is well known, Pasteur reduces the period of incubation of rabies by inoculating direct into the brain. The poison is thus at once fixed in its bed of choice instead of having to make its way to it through various tissues (during which time it is latent), and the well-known symptoms can be produced in a few days. He has no doubt that a living organism causes rabies, which finds in the brain the conditions for its development and multiplication.

The cyclical course of diseases so originated is also dwelt on in proof of their parasitic origin. In all acute miasmatic affections the stages of disease can only be explained by the progressive multipli-

cation of a living ferment in the body. This is followed by the death of the organism, when there is recovery. In such cases there is always a stage of invasion, increase, acme, decrease, and resolution; or there are remissions, either daily or of some days, accounted for by the death of one crop of parasites, followed by a renewed access of disease when a new generation of germs is matured, and set free in the organism. In this way the remission and return of tertian or quotidian fevers and the daily hectic access of phthisis are accounted for. Chemical ferments would not act so, but would work through the whole system at once, and either kill the patient, or exhaust themselves by finding no more material to work on.

To prove this doctrine it is necessary that the presence of the parasite be constant in all materials which show themselves able to produce infection, that it can and does develop and reproduce itself in the organism of man, and that this parasitic being can alone, and isolated from every other matter contained in the infecting material, determine any given infection. To this we might add that each parasite should have distinct morphological characters; but it is well known that there is often a perfect likeness between germs, some of which are infective and some not.

The questions whether the microscopic organisms, of which we have been speaking, constitute a distinct species, or are capable of modification, and are even mutually convertible, and whether they are not found naturally in the tissues and fluids of healthy animals, have occupied some of the most acute observers of our time. Lister asserts that they are not found in healthy tissues. Bastian is of opinion that they may take their origin in unhealthy or dying processes by a method which he calls heterogenesis. Lewis has experimentally shown that by impairing the nutrition of any given organ bacteria may be made to appear, and Burdon Sanderson that they may be also made to appear in tissues of previously germless animals by exciting an intense inflammation within the peritoneum or beneath the skin by means of germless chemical agents.

Virchow, at the Medical Congress of 1881, taking the parasitic nature of certain diseases as proved, inquired whether there were not different forms of the same parasite giving rise to different affections or to modifications of the same disease, and spoke of the great interest attaching to the process of culture of germs, now well known. Büchner had by this method modified, and almost transformed, the germs of bacillus anthracis, and by a series of culture generations had developed a perfectly innocent plant, the hay bacillus. Again, taking the hay bacillus, he thought he could give it virulent properties by a sort of "undomestication," making it wild again. Thus by giving the organism a special kind of soil and a more vegetable diet it might be made innocent; by a more nitrogenous diet, and under other circumstances it might be made wild or malignant again. Virchow, again, while he believes in the difference of the kind of germs entering the body, recognizes strongly the resisting powers of the system, and the facilities given to the entrance of disease by weakness, which diminishes such resistance. Béchamp believes that germs of bacteria exist in all living and healthy animals, an opinion endorsed by Billroth. Some are of opinion (or were at the Congress) that there are no specific bacilli, as Forker, who considers that these organisms produce infection only in a secondary manner, their morphological form being indifferent. Hütter thought that there were specific modes of activity in micro-organisms, but a certain unity in all.

I must apologize for reciting these various opin-

ions, but those I have quoted are all from personal experimenters on a large scale, and their recorded judgment is representative of the varied and fluctuating views of the thoughtful on the subject in all countries. By scrutinizing their variety we shall at least learn that knowledge, while rapidly progressive, demands an impartiality of mind and a caution in decision, for the facts may not be borne out by the later experiments of to-morrow. As regards the germ theory in traumatic diseases, many hold that normal blood and tissues contain micro-organisms, and that these are not causes of disease, but become so from an abnormal increase in their number, because the fluids have become so altered as to present conditions favorable to their development. To this it is replied that Burdon Sanderson and Koch himself did not find such in healthy blood, nor did bacteria spontaneously develop in man or animals. The latter author concludes that the frequent discovery of micro-organisms in traumatic infectious disease renders their parasitic origin probable, but thinks that we should have established for every such disease a parasite with marked morphological characters, while he is so persuaded of the ultimate truth of the proposition that he says: "May there not be the possible presence of a lifeless disease ferment never yet demonstrated, or other unknown quantities?" With these unknown quantities we have, however, but little to do at present.

Before examining the latest discoveries regarding tubercle let us shortly notice some of the other parasite diseases. The bacillus of typhoid finds its principal centre in the small intestines, but it can multiply itself outside the body and penetrate living organisms by means of air, water, milk, etc. However it may have been introduced, it is found in the lymphatics of the intestine and the mesenteric glands, passing thence by the bloodvessels into the whole organism. Transfusion of blood has carried the disease from one to another, as also has taken place in malarious fever according to Crudeli. These two diseases are not considered contagious, though secondary colonies of bacilli are found in the spleen, lymphatic glands, and spinal cord. Most curious and interesting is the discovery of the specific ferment of malaria attributed to Obermeier in 1873. According to Crudeli, who in Rome has had abundant opportunities of studying the subject, the parasite is a spirillum and appears as filaments. The bacillus is sporogenous, multiplies by spores inside its filaments, which break up and gain their exit either from their centre or from one extremity or both. They require a free exposure to the air and a temperature of 20° C. for their development. They are found in all marshes and in malarious districts not marshy, and in the superincumbent air of such districts. Not only spores, but developed bacilli, are found in the air. Cuboni found them in the sweat of his hands and face when in the Pontine marshes. These spirilli move briskly in the blood, are always found during an access of fever, diminish after the access, and entirely disappear in the period of apyrexia. This has been observed in man and in apes, and Carter inoculated apes with the blood of man in malarious fever, and with the result of producing the fever. Guttman has seen the spirilli in the blood thirty hours after death, and Koch in the interior of organs. In 1879 Crudeli and Klebs appear to have satisfied themselves of these facts. In pernicious fever (the worst form of malarial fever, in which I have seen patients who fell down comatose while at work in the fields), these bacilli are most numerous in the blood and in the spleen, which is of a dark color, almost black. They are also found in the brain. Experiments in 1880-81 in Rome prove their existence in the blood in the

invasion or cold stage of the fever. A subcutaneous injection of these bacilli in rabbits and dogs produced tertian and quotidian fevers. They grew rapidly in favorable conditions, which seems to be moderate moisture, free exposure to oxygen, and a tolerably high temperature. The presence of putrid matters is hostile to their growth, so that soils which have never been manured are most favorable. It is a notable circumstance that quinine placed in the soil even in small proportions kills them. During the access of fever these bacilli get liberated into the blood and lymphatics, and the periodicity of these marsh fevers is said to be due to successive generations of parasites being sent into the blood. I would only further notice that in influenza and hay fever bacilli have been found in the nasal fossæ and frontal sinuses, a fact which led Helmholtz to treat coryza by injection of quinine. In acute rheumatic fever micrococci have been observed by Crudeli and others in the articulations and in the mitral valve. In acute pneumonia the presence of parasitic germs has been demonstrated. In syphilis germs of micrococci are held to be the essence of the disease, being found in the blood of infected persons, and in the lymphatics. Gummata are new colonies—slow of formation; and it is noticed that maladies beginning with mild symptoms find the system prepared to resist them. Inflammatory reactions in chronic infections retard their course by retaining the infective matter in their various centres, but these are in their turn preventers of the action of remedies which cannot reach the part.

Clinical Remarks

ON

PROGRESSIVE MUSCULAR ATROPHY.

By M. CHARTERIS, M.D.,

Professor of Therapeutics in Glasgow University, and Physician to the Glasgow Royal Infirmary.

In bringing this case before his clinical class at the Royal Infirmary, Dr. Charteris stated that he would simply take the patient's illness as he had written it himself, in plain and clear characters. It was an interesting autobiography of an obscure disease, and had been portrayed by an intelligent sufferer, who knew exactly his position and the prognosis of his malady. He would subsequently allude to the leading features of the disease after the patient had been removed from their presence.

"My age is twenty-four years and six months, and I am a clerk by occupation. I have been suffering for the last five years under a very distressing disease. On August 20th, 1877, I was going across the Firth of Forth in a passenger steamer when I felt a sleeping and pricking sensation in the fingers of my right hand. I thought nothing of it at the time, but next morning the same peculiar feeling was still there. I took no notice of it, however, and resumed my work on the following day. I may state that I was a shipping-clerk, exposed to all sorts of weather, and served in that capacity for four years previous to my taking this disease. I continued at my work for another six months, when I felt my fingers get tired and cramped when I wrote for a few hours at a stretch. I consequently went to a doctor, who told me it was 'writer's cramp,' and advised me to take rest. I did take rest for a few weeks, but resumed work again, and continued doing so for another three or four months, when I really felt I could not

write more than an hour without taking a rest. It was at this time twelve months (August, 1878) since first I took this disease that my left hand commenced in quite the same manner as my right. I again left off work; and at the request of a brother I had in London, went and stayed with him for a few months. During my visit I went to St. Thomas's Hospital, where I was recommended the same treatment which I had previously got—viz., rest. After a stay of a few months in London I again returned to Edinburgh, and once more resumed work. It was of no use, however, as my hands by this time were getting quite weak; and at this period, exactly eighteen months from the commencement (Dec. 1878), I first noticed a wasting of the muscles of the ball of the thumb. That is where the wasting first commenced. At this stage I determined to get the best advice I possibly could, and with that desire I called upon the late Professor Sanders, of Edinburgh, and the result of my examination was that the disease under which I was suffering was pronounced to be 'progressive muscular atrophy.' I really forget the diagnosis he made at the time, but, if I remember rightly, it was in connection with the grey matter of the anterior horns. The treatment I received was galvanism; the interrupted current applied to both hands and arms twice daily, fifteen minutes each time; medicine, strychnine and iron. He (Professor Sanders) further told me that the disease commenced either in the hands (as it did with me) or the shoulder. If the latter, it took a downward course; if the former, it took an upward course; and unless the disease was stopped it gradually progressed until ultimately it reached the heart and all was over; but the progress of the disease being slow, it would take years before it ended thus. The last experience has shown me that that theory is quite correct, as I have felt my hands slowly but surely getting worse since the commencement. Acting on Professor Sander's advice in May, 1879, I went into the Royal Infirmary, Edinburgh, and was treated there in a similar manner as prescribed by him. After a few weeks' treatment there I went home, and bathed my hands daily in sea water, also rubbing them with a coarse towel; but I regret to say that after continuing this for months I felt no marked improvement. Feeling no better, and thinking my disease was getting worse, I again, in 1880, went to the Royal Infirmary, Edinburgh, and was treated there in the same manner as before. Again returning home I stayed with my parents until the latter end of last year, when, owing to family bereavement, I was compelled to leave home and come to Glasgow. I applied for admission into the Royal Infirmary, and when admitted, was treated much in the same manner as already described. I again returned to Edinburgh, and stayed with a brother, till in April, 1882, I again went to Glasgow, and was admitted into the Western Infirmary. After a few weeks' treatment I again returned to Edinburgh, and, as before, stayed with my brother until September, 1882; when, acting on my brother's advice, I once more went to Glasgow, and was admitted into the Royal Infirmary under Professor Charteris, by whose treatment I hope to find my hands much improved before leaving. I may here state that during the time I was staying with my brother, and while I was in the hospital, I used every endeavor to get employment, but regret very much indeed to say I was unsuccessful, as my hands were much against me. I may also state that, being so much knocked about lately, and not being in a position to give myself the same care and attention as I had formerly done, I have no doubt that that has aggravated my disease very much and caused it to progress more

rapidly than it would otherwise have done had I been in a position to take proper nourishment, etc. The only hope I now have is that of getting my disease checked, and I do earnestly hope that the means used will have the desired effect."

Remarks by Dr. CHARTERIS.—The cardinal symptom in this peculiar disease, known only for twenty-four years, is atrophy, developing and progressing from certain groups of muscles and accompanied by a corresponding impairment of function. The disease, as a rule, commences in the muscles of the right arm, affecting first the interossei, so that the falling in of the interosseous spaces is perhaps one of the earliest diagnostic symptoms, along with a shrinking of the muscles of the ball of the thumb. Occasionally the disease begins in the deltoid and still more rarely in certain muscles of the trunk (pectoralis major, serratus magnus). The disease, generally commencing in the muscles of the hand, may remain stationary for some time and not proceed beyond the wrist. Gradually, however, it extends over the body, attacking symmetrical groups of muscles, with the exception of the extrinsic muscles of the eyeball and internal muscles of the ear. Occasional arrests, it would appear, in the progress of the disease by no means justify a hope of permanent improvement. The first serious danger to life occurs when the respiratory muscles are attacked and bronchitis ensues. The impediment to the breathing cannot be overcome and may lead quickly to asphyxia and death. In other cases the helplessness occasions the rapid and unavoidable progress of bedsores. Progressive bulbar paralysis is clinically nearly allied to progressive muscular atrophy, and it often complicates the disease to such an extent as to be the immediate cause of death by palsy of the muscles of swallowing and of the larynx or by thrombosis or embolism of the vertebral artery, with immediate palsy of the respiratory centres. It is a disease of middle life, and the male sex show a greater tendency to it than the female. In some cases it appears to be hereditary, and then its approach is observed usually before the twentieth year. Much controversy has existed as to whether the disease is muscular or nervous in its origin, but the weight of authority inclines to the belief that the anterior tract of grey matter of the spinal cord is affected with slow inflammation, embracing cells which are supposed to govern the nutrition of muscles—viz., trophic cells.

Clinical Remarks

ON A

CASE OF HYSTERECTOMY.

*Delivered at the Samaritan Free Hospital,
Jan. 31st, 1883.*

By G. GRANVILLE BANTOCK, M.D. Ed.

GENTLEMEN—Those of you who were not in the secret were probably curious about the median linear cicatrix which was to be seen on the patient's abdomen in the position of the usual ovarian incision. The secret is this—viz., that I had performed oöphorectomy on this patient on April 6th, 1881. At that time she was in a state of profound anæmia due to the presence of an intramural fibroid tumour of the uterus, and the operation was performed for the purpose of stopping the menstrual function, and of arresting the growth and causing the disappearance of the tumour. The uterus then

reached to the umbilicus, its cavity measured eight inches, and the tumour encroached on the cervix. The operation was by no means an easy one. The left ovary with its tube was readily secured; but the right, which lay on the surface of the tumour, and was drawn out to the length of about three inches, was with great difficulty ligatured, together with its tube. The ligatures were passed as deeply as possible, and well behind all ovarian structure; but a portion of the ovary had to be left on the stump to prevent slipping. You see there is no trace of the stump or of ovarian tissue on this side. On the left side there is a small hygroma at the site of the stump (further examination revealed a small chronic abscess as large as a hazel nut kernel containing curdy pus). You see then that the tubes and ovaries were well removed. The immediate results of the operation were of the most remarkable kind. The operation was performed under a spray of plain water, and the case ran a most favorable course as regarded temperature and pulse, and the wound healed throughout by first intention. Within forty-eight hours metrostaxis set in and continued for several weeks, at times was very free. Between the second and third weeks there was great tenderness of the spleen and enlargement to twice its normal size. In the course of a week the tenderness and enlargement had disappeared. At the end of five weeks the tumour had decreased so much in size that it extended very little beyond the pubic symphysis, and the cavity of the uterus measured only four inches. This was a result as gratifying as it was remarkable. Before she left the hospital in the seventh week the metrostaxis had ceased. She remained in London for another month, and I had an opportunity of watching the case. In about a fortnight she again began to lose blood, much to our mutual disappointment, and on examining her I had the further disappointment of finding that the uterus had again enlarged and was as big as ever. The only satisfactory part of the case was the general improvement that had taken place in the patient's appearance and the great diminution in the intensity of the hæmic murmur. For twelve months she continued to menstruate with tolerable regularity, and at times in only moderate quantity, and the improvement in her general condition was fully maintained, so that I then advised her to wait. Since then, however, the flow has been more irregular and abundant, and her general health has deteriorated in spite of the very free use of iron, ergot, gallic acid, etc., and it will give you some idea of the extent of the loss of blood when I tell you that from the beginning of November till the middle of the month of January the discharge never ceased, and was even at times very excessive. Under these circumstances, and bearing in mind the very gratifying results I have recently obtained with my present method of operating, I feel justified in recommending the operation you have just witnessed. It will give you an idea also of the progress I have made in the management of these cases to mention that in the account of the former operation I made a note that "the removal of the tumour was impossible." With regard to the operation you have just seen, apart from the adhesion of the omentum to the cicatrix, it was not facilitated by the previous oöphorectomy, as the broad ligaments had been thereby shortened and tightened.

Now this case opens up an important question which has been before us for the last two or three years—viz., the question of oöphorectomy versus hysterectomy—a question which this case goes far to settle. Some of you have probably seen or heard it recommended, even very recently, that we ought not to perform hysterectomy until oöphorectomy had been already tried and had failed. I must

say that that is a proposition which, to my mind, appears both unscientific and irrational on the face of it, and which will be "more honored in the breach than in the observance," for I believe we are already in a position to determine which are the cases suitable for oöphorectomy and which for hysterectomy. Two years ago I thought the tumour could not be removed in this case. Again, in the great majority of the cases of large tumour the ovaries cannot be reached at all, or one may be within reach but the other not. Nor should we ever dream of resorting to oöphorectomy in a case of pediculated fibroid or large multiple fibroids. Experience has already shown it to be useless in these two classes. A very remarkable case occurred to me just a year ago. On Feb. 2nd of last year I operated on a patient whose case was in all respects the counterpart of the one under review. From the relations of the growth to the uterine cavity I dared not even contemplate hysterectomy in the first instance, and I proceeded to remove the ovaries and tubes. I first attacked the left side: there the ovary was closely applied to the tumour, but by dint of great pulling I managed to secure it and the tube by a double transfixing and circular ligature. On taking away the ovary, and in my anxiety not to leave any ovarian tissue in the stump—a needless precaution—I cut the stump rather short. In the handling of the tumour, to reach the other ovary, one-half of the pedicle slipped through, and no efforts of mine were of avail to secure the bleeding vessels. I was, therefore, compelled to turn out the tumour and perform supra-vaginal hysterectomy in the way you have just seen. Had I been so unfortunate, I may say, as to secure the ovaries to my satisfaction, the patient could not have been benefited by the operation, for the tumour had already undergone that peculiar kind of cystiform degeneration which you see so well illustrated in this specimen. In addition to that, there had been hemorrhage within the uterine capsule to the extent of about two ounces, which, no doubt, accounted for the very high temperature the patient had soon after her admission. You can all imagine the probable result of leaving such a tumour as that.

It has been stated that the occurrence of metrostaxis after the operation is beneficial. Such it certainly seemed to me in this case when I witnessed the rapid diminution of the tumour, though it had the effect of prolonging the patient's stay in the hospital to a very inordinate length; but time has shown the fallacy of this idea. Nor has it received any support in other cases in my hands.

The operation of removing the ovaries, and as much of the tubes as you can—call it by what name you please—is based on the argument that you check the menstrual function and at the same time interfere with the nutrition of the growth. Mr. Lawson Tait contends that the menstrual function depends on the tubes, and not on the ovaries. That is a proposition I am not prepared to accept, and I shall await with some curiosity the evidence and arguments with which he supports his position. For the present I would content myself with pointing out that menstruation goes on when the tubes are completely occluded by acute and chronic disease, and with no more disturbance than can be much more rationally explained by the coincident state of the uterine body itself. We have yet to have explained the part played by the ovaries, and whence comes that peculiar influence—nervous or electrical as you please—which determines the marvellous regularity of appearances, recurrence, and cessation, at tolerably well-defined periods. And for the present I believe the ovaries play the most important part.

Great stress has been laid on the importance of

cutting off the blood-supply through the ovarian arteries as a means of starving the tumour, and it has been urged that as this can be effected by oöphorectomy, we ought to prefer it to the more radical hysterectomy. Various well-grounded objections to this argument present themselves. We have to bear in mind that there are two sources of blood-supply to the uterus—viz., the uterine and ovarian arteries, of which the former are the larger. Then, according to a well-known law frequently taken advantage of by surgeons, when of two sources of blood-supply one is cut off, nature steps in and restores the balance, so that the nutrition of the parts concerned is maintained. In this specimen we have positive evidence that the nutrition of the uterus and tumour was not diminished, although both ovarian arteries had been cut off. Other cases in my hands also bear me out. Again, in the great majority of cases of large tumours, it is impossible, as I have already said, to get at the ovaries. But that there are certain cases in which oöphorectomy should take the place of hysterectomy I am free to admit. Such a case is that of a small or very moderately sized intramural fibroid. In such a case oöphorectomy will, I believe, render as good service, and should be preferred because of its small risk. But when the tumour is large, I believe oöphorectomy to be as dangerous as, and in some cases even more dangerous than, hysterectomy has now become under improved methods of performing the operation.

Gulstonian Lectures

ON

STERILITY IN WOMAN.

Delivered in the Royal College of Physicians, London,

By J. MATTHEWS DUNCAN, M.D., F.R.C.P.L.,

Physician-Accoucheur and Lecturer on Midwifery at St. Bartholomew's Hospital, etc.

LECTURE II.

ITS THEORY OR CAUSATION.

MR. PRESIDENT, VICE-PRESIDENT, AND GENTLEMEN—In studying the theory, or inquiring into the causes of sterility in woman, it is advantageous to keep in mind the corresponding condition in plants and in the lower animals, for in all living beings there is more or less similarity of the sexual organs and offices, and disturbance of function in one division will throw light on disturbance in another. On this subject I have made many, but only casual, observations, and have had the privilege of conversation with gardeners and breeders, classes of men in whom are found many of remarkable intelligence and acuteness of observation. But the great storehouse of facts and references on which I rely is Darwin's "Variation of Animals and Plants under Domestication." Plants and some animals propagate otherwise than by sexual generation, but it is only the sterility arising from disturbance of the regular course and consequences of sexual union that has a direct or nearly direct bearing on the present inquiry. The sterility of hybrids, which, considering the theory he is supporting, forms naturally the main study of Darwin, is of comparatively little interest to us, and will not be hereafter referred to, but many of the principles of sterility find strong support in the special sterility of hybrids.

Viewing the subject generally, we may anticipate a great result by pointing out the paramount prevalence and potency of constitutional conditions

as causes of sterility. Such are cold and heat, overfeeding and underfeeding, youth and old age, degradation of general health, confinement, and interbreeding.

Local conditions occur in plants that are quite sufficient to account for or cause sterility. Such are contabescence of anthers, monstrous flowers, double flowers, seedless fruit. These local conditions are the result of the general or constitutional conditions of the individuals in which they occur; and they have their place rather in the results of sterility, or of the conditions producing sterility, than in the causes of sterility. They have their analogues in such abortions, dead fetuses, unhealthy offspring, or monstrous products of animals as are believed to be results of what may be called the sterile diathesis. The causes of sterility are causes of these imperfections, and for that reason they are referred to the sterile tendency. They do, indeed, constitute the sterility to be accounted for. Thus, to wander into hybridism for an example, it is an observation of Gärtner that hybridism in plants, a great cause of sterility, produces also a strong tendency in flowers to become double.

In the vegetable kingdom everyone has observed that source of sterility which may be, no doubt nearly truly, designated a degradation of general health. A plant covered with flowers is brought from a house where its fertility has been stimulated to the highest degree, and placed as an ornament in a sitting-room, where it remains till its charms are lost, and the result is such an injury to its constitutional vigor that it is sterile, or nearly sterile, for one or for several subsequent seasons. Its fertility may never be restored, or only after several years of the medical care of a skilful gardener. The scarlet geraniums which are brought from their healthy homes in full bloom to adorn the houses of inhabitants of densely populated cities soon show the injurious influence of their new surroundings, however well they may be cared for; their flowers become less numerous, or are altogether wanting; then their leafage diminishes greatly in quantity, and their existence becomes a mere lingering. A rose garden, lately in a suburban position near London, gets surrounded by the growing city, and gradually as the buildings increase the fertility of the roses diminishes; the garden becomes useless. Some of our finest forest trees, and among them some plants, grow beautifully in our squares, producing wood in even exaggerated quantity, and a clothing of leaves sufficient for ornament; but there is no wealth of leaves, and there is no seed. In some cases an exception makes the rule more striking, as when a cherry tree in the heart of the city of London lately produced flowers and matured its fruit, so far as maturity is indicated by beauty, size, and taste.

Practical gardeners attribute sexual injury to overstimulation by manure, or what they call overfeeding. This ordinarily produces great growth of the tissues, and when this is restrained by judicious pruning, it forces out a large or excessive crop of flowers and subsequent fruit. In the language of Spencer, there is produced by overfeeding an excess of individuation, the restraint of which results in excess of genesis. The natural tendency of the overfeeding of plants is to produce a degree of relative sterility; and this may show itself in paucity of flowers, or it may show itself in the production of those double, or monstrous, or abortive flowers which are so much admired. The opposite result is produced by moderate or full feeding. Then, in mature plants there is not great growth of tissues, but rather a production of fruit. Sometimes the plant, without assignable cause, but

especially if underfed, has an exaggerated production, and is said to run to seed; and, from whatever it may arise, it in a reflex manner injures the plant, which consequently becomes blighted and often dies. Excessive production here seems to take the place of sterility.

The following is an interesting illustration of the effect of overfeeding and of moderately feeding or underfeeding a vine, and it is important because it specifies a particular local condition or disease which is apparently the cause of the infecundity of the overfed plants, and so indicates a line of investigation which may with advantage be pursued in other examples of sterility. In a recent letter from Mr. Thomson, the well-known vine cultivator, he writes:—"A circumstance has arisen in my own experience that I have never seen noticed in print. A vine called the Alnwick seedling, if grown vigorously in rich soil, fails to set its fruit even when aided. This failure is caused by the exudation from the female organ of a dewdrop of sap, which moistens the pollen, and it does not descend through the pistil and impregnate the ova. When the vine is grown in poor soil the dewdrop does not appear, and impregnation takes place; seeds are formed in perfection, but the pulp for which the grape is grown is almost absent. I know (he adds) no other grape affected in the same way or subject to the same influences."

I know no good account of the sterility of plants as regulated by age, but the influence of age is well recognized. A young fruit tree bears no fruit, or very little, and that little imperfect, and the careful gardener does not permit it to bear much or even a little, believing that fruit bearing injures growth and diminishes future fertility. The influence of old age and decay in fruit-bearing trees is also well known: the fruit is ill developed, and there is little of it.

"All know," says Spencer, "that a pear tree continues to increase in size for years before it begins to bear, and that, producing but few pears at first, it is long before it fruits abundantly. A young mulberry, branching out luxuriantly, season after season, but covered with nothing but leaves, at length blossoms sparingly, and sets some small and imperfect berries, which it drops while they are green; and it makes these futile attempts time after time before it succeeds in ripening any seeds. But these multiaxial plants, or aggregates of individuals, some of which continue to grow while others become arrested and transformed into seed-bearers, show us the relation less definitely than certain plants that are substantially, if not literally uniaxial. Of these the cocoa-nut may be instanced. For some years it goes on shooting up without making any sign of becoming fertile. About the sixth year it flowers, but the flowers wither without result. In the seventh year it flowers and produces a few nuts, but these prove abortive, and drop. In the eighth year it ripens a moderate number of nuts, and afterwards increases the number, until, in the tenth year, it comes into full bearing. Meanwhile, from the time of its first flowering, its growth begins to diminish, and goes on diminishing till the tenth year, when it ceases."

The evil influences of interbreeding is a subject too extensive to enter upon at any length. In plants it is corroborated by the well-known advantage of crossing of varieties. But it needs no confirmation, for there are self-impotent plants, plants more thoroughly fertilized by a nearly allied species than by pollen of their own species, and there are the wonders of dimorphism with sterility arising from union of individuals not only of the same species but of the same form. In the works of horticulturists is to be found ample evidence that

interbreeding of plants tends to weakness, malformation and sterility.

The influence of heat and of cold is, in plants, well illustrated by the failure of most Alpine species to produce flowers and fruit in lowland gardens, and the same failure of lowland plants as they ascend the sides of mountains. A walk in the highlands will show the pines thriving on the hillsides and well covered with cones, but as greater altitudes are reached the trees are observed to become stunted and the fruit entirely to fail.

The abortion-like sterility of plants is illustrated by the bearing of double flowers, of flowers whose seeds do not ripen, or whose seeds, though apparently perfect, are incapable of germination and growth. In some of the cases of seedless fruit and of fruit with few seeds or with one seed, or with imperfect seed, we have also abortion and at the same time a fine illustration of the working, locally, of the opposition between individuation and genesis. The whole plant, as the vine or the pear-tree, may have the appearance of health, and its fruit alone is unnatural. The tissues of the fruit-capsule are enormously developed, while the seeds have disappeared or are reduced to one or a small number. The luscious pear or the juicy grape are masses of hypertrophy or myxomatous-like degeneration while the seeds are the subject of extreme hypoplasia. Gardeners generally ascribe these results to overfeeding and overstimulation by manures and heat, but Darwin is more cautious, and in most cases does not analyze the causes further than is implied in "unnatural conditions of life." No one, according to Lindley and Darwin, has produced double flowers by promoting the perfect health of the plant.

Before leaving vegetable physiology I would point out the frequent occurrence in plants of seeds which, though apparently perfect, will not germinate; they cannot be distinguished from their neighbors otherwise than by their incapacity for growing. The same failure to grow is often observed under closely similar circumstances in the eggs of the fowl and of other birds; they cannot be hatched, although no imperfection is discoverable in them. That there are such ova in other animals and in woman is highly probable, but in them the completeness of the demonstration is unattainable.

Very little is known of the sterility of animals, and it is easily understood that reliable observations can only, with great difficulty, be made on them, especially in a state of nature. Many authors, and latterly Darwin and his collaborators, have paid much attention to the great subject of the sterility of hybrid animals. Observations and experiments in this department are made chiefly on domestic animals, or wild animals in confinement, and each experiment has a high value. But the sterility of ordinary domestic animals has been little studied. In herds of fine heifers and cows, and in mares, it is occasionally exhibited, but I have no data as to its frequency; and in cattle, at least, observations are imperfect, the animal that, by sterility of one season, disappoints its owner, being generally at once fattened for the butcher.

It is a well-known belief among breeders, which may be historically traced to ancient times, that when the female of any kind is made to breed when very young, she does so at the expense of permanently preventing her own growth to perfection, and she will likely produce offspring that is not of the best quality. This failure is well illustrated in the case of the common fowl and of the turkey, the progeny of chickens and of turkeys one year old being not the best of their kind, and specially

difficult to rear. Fanciers breed these animals from a female two years and a male three years old. The occurrence of sterility in early and in elderly life is clearly seen, and its degree easily made out in pluriparous mammals, as the dog and pig, and in birds whose broods can be counted and whose yearly production of eggs can be also numbered. This subject will be discussed fully when we come to consider pluriparity in woman.

Overfeeding, or the production of fatness or of obesity in the female, is well known to be hostile to fertility, to be an illustration of the opposition of individuation to genesis. By special feeding and fattening turkeys and common fowls the hen-wife arrests almost completely the production of eggs. They may also be made fewer by starving the birds, and not fewer only but also smaller. These birds when highly fed sometimes exhibit excessive productiveness, two eggs being laid daily, an instance of great intensity of fertility; but this is not regarded with favor, having, I am told by a turkey fancier, an injurious influence, in their case, by delay of the commencement of laying in the season following that of the excessive production. The breeder of cattle prevents by careful management the fattening of the females.

In respect of feeding, comparisons are made between the relative sterility of wild animals and the comparative fertility of domesticated or confined animals of the same species, but the comparisons are not quite satisfactory from the intermixture of the influences of food and of domestication or confinement; and again, in the comparisons of animals fed on rich and on poor pasture, sufficient care is not taken to ensure that the compared animals are of the same breed. With this previous reflection I subjoin an interesting passage from Spencer's chapter on nutrition and genesis: "Clear proof," says he, "that abundant nutriment raises the rate of multiplication (and *vice versa*) occurs among mammals. Compare the litters of the dog with the litters of the wolf and the fox. Whereas those of the one range in number from six to fourteen, the others contain respectively five or six or occasionally seven, and four or five, or rarely six. Again, the wild cat has four or five kittens, but the tame cat has five or six kittens two or three times a year. So, too, is it with the weasel tribe. The stoat has five young ones once a year. The ferret has two litters yearly, each containing from six to nine; and this notwithstanding that it is the larger of the two. Perhaps the most striking contrast is that between the wild and tame varieties of the pig. While the one produces, according to its age, from four to eight or ten young ones, once a year, the other produces as many as seventeen at a litter; or, in other cases, will bring up five litters of ten each in two years—a rate of reproduction that is unparalleled in animals of as large a size. And let us not omit to note that this excessive fertility occurs where there is the greatest inactivity—where there is plenty to eat and nothing to do. There is no less distinct evidence that among domesticated mammals themselves, the well-fed individuals are more prolific than the ill-fed individuals. On the high and comparatively infertile Cotswolds it is unusual for ewes to have twins, but they very commonly have twins in the adjacent rich valley of the Severn. Similarly, among the barren hills of the west of Scotland, two lambs will be born by about one ewe in twenty; whereas in England, something like one ewe in three will bear two lambs. Nay, in rich pastures, twins are more frequent than single births; and it occasionally happens that, after a genial autumn and consequent good grazing, a flock of ewes will next spring yield double their number of lambs—the triplets balancing the uni-

para. So direct is the relation, that I have heard a farmer assert his ability to foretell, from the high, medium, or low condition of an ewe in the autumn, whether she will next spring bear two, or one, or none."

An interesting department of the sterility of animals is that which results from confinement. This seems specially to affect what are vaguely designated the noble animals. Those which are sterile show great variations; some disdain to cohabit or have lost sexual desire; others have increase of sexual appetite, and cohabit freely or excessively, but without impregnation resulting, or with the result very rarely following. Some if impregnated bring forth only abortions, or young which are dead-born, or, if alive, feeble and ill-formed. There is, for instance, as Shorthouse has pointed out, a common occurrence of cleft palate in the lion's cubs born in the Zoological Gardens.

Among birds in confinement there are many good examples of change of sexual habits and of sterility. In some cases they have no eggs, or, if they produce, they have only comparatively few, or they may neglect the eggs when produced, or the eggs duly cared for may be incapable of being hatched. This abortional sterility arising from imperfection of eggs as a result of confinement is well proved by experiments made in France on the common fowl. When these birds were allowed considerable freedom, 20 per cent. of the eggs failed to be hatched; when less freedom was allowed, 40 per cent. failed; when closely confined, 60 per cent. were not hatched.

The power of temperatures that are not according to an animal's nature to induce sterility is no doubt very great. Darwin mentions that Mr. Miller, a former superintendent of the Zoological Gardens, believed that the sterility of the carnivora there was increased by increase of exposure to air and cold. In winter, inadequately sheltered cows either cease to give milk or give it in diminished quantity. "And," says Spencer, "though giving milk is not the same thing as bearing a young one, yet, as milk is part of the material from which a young one is built up, it is part of the outlay for reproductive purposes, and diminution of it is a loss of reproductive power." Failure to maintain the cow's heat may entail such reduction in the supply of milk as to cause the death of the calf. Hard living, says Darwin, retards the period at which animals conceive, for it has been found disadvantageous in the northern highlands of Scotland to allow cows to bear calves before they are four years old. Roulin found that in the hot valleys of the equatorial Cordilleras sheep were not fully fecund.

The common fowl will not breed in Greenland or Northern Siberia. "In this country it is fed," says Spencer, "through the cold months, but nevertheless, in midwinter it either wholly leaves off laying, or lays very sparingly. And then we have the further evidence that if it lays sparingly, it does so only on condition that the heat, as well as the food, is artificially maintained. Hens lay in cold weather only when they are kept warm. To which fact may be added the kindred one that when pigeons receive artificial heat they not only continue to hatch longer in autumn, but will recommence in spring sooner than they would otherwise do."

On the subject of the interbreeding of animals there is a vast body of opinion as well as of facts showing its power in producing monstrosity and its ally sterility. "If we were," says Darwin, "to pair brothers and sisters in the case of any pure animal, which from any cause had the least tendency to sterility, the breed would assuredly be lost in a few generations." Elsewhere he shows

that "long-continued close interbreeding between the nearest relations diminishes the constitutional vigor, size, and fertility of the offspring; and occasionally leads to malformations, but not necessarily to general deterioration of form or structure. This failure of fertility shows that the evil results of interbreeding are independent of the augmentation of morbid tendencies common to both parents, though this augmentation no doubt is often highly injurious. Our belief that evil follows from close interbreeding rests to a large extent on the experience of practical breeders, especially of those who have seen many animals of the kind which can be propagated quickly; but it likewise rests on several carefully recorded experiments. With some animals close interbreeding may be carried on for a long period with impunity by the selection of the most vigorous and healthy individuals; but sooner or later evil follows. The evil, however, comes on so slowly and gradually that it easily escapes observation, but can be recognized by the almost instantaneous manner in which size, constitutional vigor, and fertility are regained when animals that have long been interbred are crossed with a distinct family."

Regarding the very remarkable subject of sterility of sexual connection with special individuals only, Darwin says:—"It is by no means rare to find certain males and females which will not breed together, though both are known to be perfectly fertile with other males and females. We have no reason to suppose that this is caused by these animals having been subjected to any change in their habits of life. . . . The cause apparently lies in an innate sexual incompatibility of the pair which are matched. Several instances have been communicated to me by Mr. W. C. Spooner (well known for his essay on Cross-breeding), by Mr. Eyton, of Eyton, by Mr. Wicksted, and other breeders, and especially by Mr. Waring, of Chilsfield, in relation to horses, cattle, pigs, foxhounds, other dogs, and pigeons. In these cases, females which either previously or subsequently were proved to be fertile, failed to breed with certain males, with whom it was particularly desired to match them. A change in the constitution of the female may sometimes have occurred before she was put to the second male; but in other cases the explanation is hardly tenable, for a female known not to be barren has been unsuccessfully paired seven or eight times with the same male, likewise known to be perfectly fertile. With cart-mares, which sometimes will not breed with stallions of pure blood, but subsequently have bred with cart stallions, Mr. Spooner is inclined to attribute the failure to the lesser sexual power of the racehorse. But I have heard from the greatest breeder of racehorses at the present day, through Mr. Waring, that it frequently occurs with the mare to be put several times during one or two seasons to a particular stallion of acknowledged power, and yet prove barren, the mare afterwards breeding at once with some other horse. These facts are worth recording, as they show, like so many previous facts, on what slight constitutional differences the fertility of an animal often depends."

Before leaving the subject of the causes of sterility of animals, I quote a passage from Darwin regarding the results of confinement. "Sufficient evidence," says he, "has now been advanced to prove that animals, when first confined, are eminently liable to suffer in their reproductive systems. We feel at first naturally inclined to attribute the result to loss of health, or at least to loss of vigor, but this view can hardly be admitted when we reflect how healthy, long-lived, and vigorous many animals are under captivity, such as parrots, and hawks when used for hawk-

ing, chetahs when used for hunting, and elephants. The reproductive organs themselves are not diseased, and the diseases from which animals in menageries usually perish are not those which in any way affect their fertility. No domestic animal is more subject to disease than the sheep, yet it is remarkably prolific. The failure of animals to breed under confinement has been sometimes attributed exclusively to a failure in their sexual instincts; this may occasionally come into play, but there is no obvious reason why this instinct should be specially liable to be affected with perfectly tamed animals, except, indeed, indirectly, through the reproductive system itself being disturbed. Moreover, numerous cases have been given of various animals which couple freely under confinement, but never conceive, or, if they conceive and produce young, these are fewer in number than is natural to the species. In the vegetable kingdom instinct of course can play no part, and we shall presently see (he says) that plants, when removed from their natural conditions, are affected in nearly the same manner as animals. Change of climate cannot be the cause of the loss of fertility, for, whilst many animals imported into Europe from extremely different climates breed freely, many others, when confined in their native land, are completely sterile. Change of food cannot be the chief cause, for ostriches, ducks, and many other animals, which must have undergone a great change in this respect, breed freely. Carnivorous birds, when confined, are extremely sterile, whilst most carnivorous mammals, except plantigrades, are moderately fertile. Nor can the amount of food be the cause, for a sufficient supply will certainly be given to valuable animals, and there is no reason to suppose that much more food would be given to them than to our choice domestic productions which retain their full fertility. Lastly, we may infer, from the case of the elephant, chetah, various hawks, and of many animals which are allowed to lead an almost free life in their native land, that want of exercise is not the sole cause. It would appear that any change in the habits of life, whatever these habits may be, if great enough, tends to affect in an inexplicable manner the powers of reproduction. The result depends more on the constitution of the species than on the nature of the change; for certain whole groups are affected more than others; but exceptions always occur, for some species in the most fertile groups refuse to breed, and some in the most sterile groups breed freely. Those animals which usually breed freely under confinement rarely breed, as I was assured, in the Zoological Gardens, within a year or two after their first importation. When an animal which is generally sterile under confinement happens to breed, the young apparently do not inherit this power; for had this been the case, various quadrupeds and birds which are valuable for exhibition would have become common. Dr. Broca even affirms that many animals in the Jardin des Plantes, after having produced young for three or four successive generations, become sterile; but this may be the result of too close interbreeding. It is a remarkable circumstance that many mammals and birds have produced hybrids under confinement quite as readily as, or even more readily than, they have procreated their own kind. Of this fact many instances have been given, and we are thus reminded of those plants which when cultivated refuse to be fertilized by their own pollen, but can easily be fertilized by that of a distinct species. Finally, we must conclude, limited as the conclusion is, that changed conditions of life have an especial power of acting injuriously on the reproductive system. The whole case is quite peculiar,

for those organs, though not diseased, are thus rendered incapable of performing their proper functions, or perform them imperfectly.

Finally, Shorthouse has pointed out in mares the close alliance between sterility, abortion, and that kind of excessive fertility which is demonstrated by twinning. I quote the examples

In woman sterility varies in amount according to the age at marriage. This is shown by the table which I compiled from the data of Edinburgh and Glasgow in 1855. (See Table IX.) It is evident that this table gives only an approach to the truth, for in its second column there is an excess of children over marriages that cannot have been. In-

TABLE IX.

Showing the Variations of Sterility according to the Age at Marriage.

Ages of wives at marriage....	15-19	20-24	25-29	30-34	35-39	40-44	45-49	50, etc.	Total.

which he gives in the *Sporting Times* for Dec. 12th, 1874; and, as adding to the force of the evidence, it is to be remembered that in the mare twinning is a far rarer event than in woman and the cow: in these it occurs about once in 80 pregnancies; in the mare it is said to be only once in 400:

Miserrima, barren in 1855, 1858, 1867, 1870, and 1871; slipped foal in 1856, 1859, and 1863; had dead twins in 1860 and 1862.

Caricature, barren in 1852, 1854, 1855, 1861, 1867 and 1871; had twins in 1856 and 1863; slipped foal in 1866.

Legerdmain, barren in 1852, 1859, 1864, and 1866; slipped foal in 1849; slipped twins in 1856, 1860, and 1862.

Crystal, barren in 1858, 1860, and 1865; in 1866 slipped twins.

Slander, barren in 1851, 1854, 1864, 1865, and 1866; slipped twins in 1857.

Thimblebrig, barren to two horses in 1867; slipped twins in 1869.

Zoe, barren in 1865, 1866, 1867, 1868, 1869, 1870, and 1871; slipped foal in 1860.

No. 1, barren in 1865 and 1868; slipped foal in 1867.

No. 5, barren in 1856, 1858, 1860, 1864, and 1866; slipped foals in 1862 and 1868.

No. 7, barren in 1857 and 1860; had twins in 1858.

No. 8, barren in 1867; had twins in 1861.

No. 9, barren in 1858, 1860, 1864, and 1867; had twins in 1868.

No. 10, barren in 1858, 1860, and 1864; had twins in 1861.

No. 11, barren in 1856, 1863, and 1864; slipped foals in 1859 and 1865.

I know no observations worth quoting as to the special sterility of male lower animals, and the subject requires much further investigation. It is not quite a new subject, for it is popularly believed that certain stallions are often inefficacious; and accordingly breeders, in their advertisements, take care to add to the other qualifications of a named horse that he is a "sure getter."

congruity of this kind is not only accounted for, but to be expected, from the manner in which the table is made up. The number of marriages in Edinburgh and Glasgow in 1855 at different ages of the wives are compared with the numbers of first living children born in the same year to wives married at the same ages in that year or previously, and the number of sterile wives is got by subtracting the latter figures from the former. The comparison is of the first births of one year with the marriages of the same year, while they were mostly the result of the marriages of the former year, and the table is consequently imperfect. It must be remembered that this table, like the others from the same source, gives the title of first children to the first born living, excluding the dead from the reckoning, another manifest source of error. But there can be no doubt, I think, of the conclusion as to age which is derivable from it—that women married under twenty years of age have much more sterility than women married from twenty to twenty-four inclusive, and that the sterility of marriages before twenty is less than the sterility of marriages after twenty-four, and that of marriages after twenty-four the sterility increases with the age at marriage. A nearly similar conclusion is derivable from the Statistics of Providence published by Snow.

The relative sterility of women at different ages is in part shown by their slowness to become mothers, or the length of interval between marriage and childbearing; and this is found to tally with the sterility according to age which I have just stated. I give another Edinburgh and Glasgow table embodying the facts bearing on this. (See Table X.) Those married below twenty years of age were longer in married life before becoming mothers than those married between twenty and twenty-four inclusive. These latter showed the highest fecundity and quickness to commence bearing children. Those again married after twenty-four were slower than their predecessors, and the slowness increased with every additional quinquennium after that of twenty to twenty-four.

In the quinquennaid preceding twenty I can give for each single year the increasing delay of childbearing as age decreased. Table XI., from the Edinburgh and Glasgow data, shows this relative sterility of early ages.

TABLE XI.

Showing the Initial Fecundity of Women under Twenty Years of Age within the First Two Years of Marriage.

Ages of wives newly married.....	16	17	18	19
No. of wives newly married.....	43	108	225	314
No. of wives mothers within two years of marriage.....	4	27	98	177
Proportion of latter to former is 1 in...	10·7	4·0	2·3	1·8
Proportion after correction for immaturity is 1 in.....	7·7	3·3	2·1	1·7
Or percentage.....	12·90	30·00	46·44	57·84

At this point of the inquiry as to the influence of age I interpolate an argument as to the influence of marriage or cohabitation in causing sterility. Although it seems at first sight absurd to rank marriage among the causes of sterility, yet the conclusion that it is so, at least in the very young, appears to be inevitable. For if the women married under twenty are more sterile than those married at twenty to twenty-four, and are also more relatively sterile so far as delay of childbearing shows this quality, then, if the marriages of the very young—that is, of those under twenty—had been delayed till the next quinquennaid, they would in greater numbers have shown fertility and shown it also more quickly. Now, as the only difference known between those of twenty to twenty-four and those younger is age at marriage, we may reasonably conclude that premature marriage was the cause of the sterility. There may be some analogous injurious influence of too long delayed marriage upon the elderly, and the delay of commencing childbearing may point to it; but we cannot say of them, as we do of the youngest married, that if they had still further delayed marriage they would have had more chance of being mothers! Some further reference to this evil influence of marriage, and attempt at explanation, will be found in the discussion on sexual pleasure.

I might here adduce evidence of the influence of age which is found in the weight and length of the children produced, the length and weight rising with the age of the mother to its climax in the children born to mothers between the ages of twenty and twenty-nine inclusive, and then again falling as the age of the mother increases above twenty-nine. This is a matter tested by too delicate variations of length and weight to be, as yet, quite relied on, and great authorities have indeed contested its truth, Hecker, for instance, alleging that the measurements increase with the age of the mother in a direct sort of proportion. But I have Aristotle on my side. "Premature conjunctions," says he, "produce imperfect offspring, females rather than males, and these feeble in make and short in stature. That this happens in the human race," he adds, "as well as other animals, is visible in the puny inhabitants of countries where early marriages prevail." The general tenor of the evidence is, indeed, very strong, in showing a concurrence of sterility, monstrosity, feebleness, and smallness, and on that account I still hold that diminished length and weight of children accom-

pany the diminished fertility of the premature and post-mature women.

It is matter of regret that we can present no demonstration of the influence of age on fecundity founded on the frequency of abortions and of ill-formed children. But we approach near to such evidence, and may guess what it would yield when we present the facts, scanty though they be, as to

TABLE XII.

Showing the Mortality of Children Born in Marriages formed at Different Ages.

Years elapsed since birth of first child.	Mortality per cent. of the children born to marriages formed at ages—			
	16-20	21-25	26-30	31-35
10	36·87	37·09	37·89	35·48
20	47·44	43·10	44·36	16·67
30	53·03	43·89	48·53	64·29
40	63·12	57·14	68·00	50·00

rearing of children and as to idiocy. Table XII., derived from the data obtained by the Statistical Society in St. George's-in-the-East, is the only body of facts as to the rearing of children born of mothers at different ages that I know of. It shows a diminished amount of rearing of children of the sterile ages. The sterility or weakness of reproduction by mothers of sixteen to twenty years of age is shown by the failures in rearing, and increased failures in rearing appear again as the sterile ages above twenty-five are entered on, the failures to rear increasing with the age of the mothers just as sterility increases at the same ages.

We suppose that, from the time of their birth, the children of these observations were tended with the same care or desire of the mothers to act fairly by them; and that we must look to some cause of the failure to rear in the reproductive arrangements. Now, here we include the nourishment of the child among the reproductive processes, while in our other studies of sterility we stop at its birth, or, if we proceed further, we consider only conditions presumably already established or commenced at the time of birth, such as idiocy. The child is naturally fed upon its mother's milk and the feeding is an extra-uterine continuation of the previously otherwise conducted nutrition of the foetus. Nursing is part of the reproductive process. The failure to rear may be a result of imperfection of the foetus, now a child, or it may be the result of the imperfection of the mother as a nurse. I know no method of disentangling the results of these two causes, but the potency of imperfect nursing is undoubted. It is a universally recognized rule in the selection of wet nurses that very young or elderly mothers are to be avoided.

Imbeciles and idiots may be so from original or innate causes, sometimes called developmental, or from injury or other accidental causes. The undoubted frequency of accidents at birth or other injuries as causing imbecility and idiocy introduces an element which should be subtracted with a view to the ascertainment of the influence of the mother's age in the production of the mental weakness; but, although in individual cases the two kinds, the developmental and accidental, may with much assurance be distinguished, I know no way of doing so in the statistics to be adduced. Authors on this subject, especially Little, attach great importance to the resuscitation of the still-born as an accidental cause of idiocy, and it may

be so; but I am disposed to attribute the necessity for resuscitation partly to the feebleness of the imbecile child produced. Among Langdon Down's 2,000 cases, 400, or 20 per cent., were born in a state of suspended animation, and 40 per cent. of these 400 were first children. At all events, it will not be disputed that the great majority of idiots and imbeciles are so from innate or developmental, not accidental, causes acting during or after birth.

Among Mitchell's 443 idiots and imbeciles 138 were first-born; among Wilbar's 675 there were 191 first born; among 100 of Beach's, 20; among 2,000 of Down's, 480. Or among 3,218, 829, or about 26 per cent., were first born, and presumptively born of young mothers.

"Among 443 idiots and imbeciles consecutively examined," says Mitchell, "I found 138 first born, or 31·1 per cent.; and 89 last born, or 20·1 per cent. When it was known, however, that almost every sixth idiot in Scotland was illegitimate (663 idiots and imbeciles, giving 108 illegitimate, or 17·1 per cent.), it was thought that an element of disturbance was probably thus introduced into the foregoing figures which might affect their value. The great majority of illegitimate children are known to be first-born and only children; while not a few of them are last born, though the last of a small number of pregnancies—say of two or three. It was therefore thought desirable that a fresh series of observations should be made, excluding the illegitimate, and dealing only with those born in marriage. It was also thought well to confine these observations to those cases in which not more than one idiot occurred in a family, and in which the idiocy was noticed very soon after birth—that is, in which it was probably congenital. Further, no cases were accepted but those in which the mothers at the time of the inquiry had passed the age of childbearing, though some of them, I think, were widows before that age was reached. All these restrictions made it difficult to obtain a large series of observations, and account for their number not exceeding 85—44 males and 41 females. I sent my results in detail to Dr. Matthews Duncan, who kindly drew up for me the two tables embodying the facts in a way

TABLE XIII. (from Arthur Mitchell.)

Showing the Comparative Frequency of Births of Idiots, and of all Births, in First and Subsequent Pregnancies.

Number of pregnancy.	Percentage of all births.	Percentage of idiot births.
First.....	22·8	33·0
Second.....	17·7	18·8
Third.....	15·5	17·6
Fourth.....	12·1	2·4

Tenth.....	1·3	7·0
Eleventh.....	·9	3·5

which makes their teaching apparent." (See Table XIII.) "This table is read in this way: Of all the children born in Edinburgh and Glasgow in 1855, 22·8 per cent. were first pregnancies; while of the 85 idiots, 33 per cent. were first pregnancies, and so on. What the table appears to teach is briefly this—that idiocy is more likely to occur among first and latest (seventh to eleventh) pregnancies than among others. This is substantially the same thing as was taught by the first inquiry, which included 443 cases, and in which all that

was asked was whether the patient was first born or last born."

Similar evidence is derivable from the data given by Langdon Down, but in regard to them we have not the same assurance of the circumstances of the collections as is given by Mitchell in regard to his. Down's data are given in Table XIV.

Thirteenth.....	·2	3
Fourteenth.....	·06	1

Fortunately Mitchell gives the age of the mother at the time of the birth of the idiot, and the result is very striking. Down does not give the age of the mother in his collection, but considering the excess of primiparity and the very large proportional number of pregnancies of high figure among them, we can have no doubt they would yield a like result.

"The same eighty-five cases," continues Mitchell, "are used in Table XV, which were used in Table XIII. This table is read thus:—Of all the children born in Edinburgh and Glasgow in 1855, 22·6 per cent. were born of mothers whose ages were from twenty to twenty-four years, while of the eighty-five idiots 25·8 per cent. were born of mothers of corresponding ages, and so on. What we learn from the table is this: that mothers under twenty-four years of age and above thirty-five are those more specially liable to have idiocy in their children."

Several times I have been told by men of experience that an old bitch often ends her career of breeding by a dead and premature pup. Whitehead regards those pregnancies which occur near the termination of the fruitful period in women as being the most commonly unsuccessful, and Arthur Mitchell has connected the occurrence of idiocy in a child to the circumstance of its being the last born of its mother. "That in the mother," he remarks, "which leads to the miscarriage may lead also to the idiocy, and the only connection may be one through a common cause. It frequently happens," he adds, "that between the birth of the idiot and that of the child which precedes or follows, an interval occurs which is much longer than usual, or that after the birth of the idiot permanent sterility appears. Again, when the idiot is born eighteen or twenty-four months after the preceding child, but when for six or seven years thereafter no impregnation occurs, he thought there was reason to suspect that the imperfection in reproductive power, which showed itself in the idiot, had merely another and fuller expression in the subsequent barrenness. And so also when permanent sterility follows. In many cases indications of barrenness preceded the birth of the idiot, and became permanent thereafter."

We have alluded to prevalent opinions that the last born of a woman is specially liable to be a miscarriage, or a weak child, or an idiot, and

female rather than male, and have shown that these opinions have considerable support from facts. We have also spoken of the only-child sterility, the mothers being in Ansell's collection at the high mean age of thirty-one. Now, in addition, there is some, though imperfect, evidence that such children, especially if female, are not merely illustrations of one-child fertility or only-child sterility, but are also the last of their race. They represent a family's last effort at continuation of its line. Girls in such a position are often heiresses, though not certainly single children, and this circumstance has enabled Galton to

"I find that among the wives of peers, 100 who are heiresses have 208 sons and 206 daughters, 100 who are not heiresses have 336 sons and 284 daughters. The latter shows how exceedingly precarious must be the line of a descent from an heiress. One-fifth of the heiresses have no male children at all; a full third have not more than one child; three-fifths have not more than two."

In Galton's statement of the actual infertility of heiresses there is observable a remarkable comparative paucity of male issue—a fact which goes, like many others, to confirm the ancient and still

TABLE XV. (from Arthur Mitchell.)

Showing a Comparative Percentage of the Children Born at Different Ages of Mothers to all Children Born, and of the Idiots Born at Different Ages of Mothers to all Idiots Born.

Age.....	20-24	25-29	30-34	35-39	40-44	45-49
Percentage of all children...	22·62	39·99	23·61	14·76	5·15	0·58
Percentage of idiots.....	25·88	25·88	10·68	10·58	23·53	3·53

follow up their history and to show their infertility. I know several remarkable cases of single children of this kind, feeble, rich, childless, the last of their race; but a collection of cases forms stronger evidence than any scattered good examples. Speaking of marriages of heiresses as peculiarly unprolific, Galton remarks: "We might, indeed, have expected that an heiress, who is the sole issue of a marriage, would not be so fertile as a woman who has many brothers and sisters. Comparative infertility," he adds, "must be hereditary in the same way as other physical attributes, and I am assured it is so in the case of the domestic animals." In addition to other strong evidence of the same kind, Galton found in a partial search through the peerage, a total of fourteen heiress-marriages among seventy peers, resulting, he says, in eight instances of absolute sterility, and in two instances of only one son. "I tried the question from another side," he continues, "by taking the marriages of the last peers and comparing the numbers of the children when the mother was an heiress with those when she was not. I took precautions to exclude from the latter all cases where the mother was a co-heiress, or the father an only son. Also, since heiresses are not so very common, I sometimes went back two or three generations for an instance of an heiress marriage. In this way I took fifty cases of each. I give them below, having first doubled the actual results, in order to turn them into percentages:—

TABLE XVI. (from Galton.)

prevalent opinion that relative sterility or weakness of reproductive energy tends to the production of females rather than males. This department of the study of sterility I shall not enter on, the causes of the excess of females over males in all births being the subject of an extensive literature, and its relations being too numerous and complicated for advantageous discussion in this place. But I may state that I have long been impressed with a belief, in accordance with the chief pertinent facts, that the excess of female births is due to the prevalence of a degree of weakness of reproductive energy. Excess of female births is coincident with other evidences of sterility.

We have already given reason for believing that when a woman bears above ten of a family she shows an unnatural or excessive amount of fertility; and this belief is corroborated by the demonstration we now propose to give that excessive families occur chiefly in women who are married in the sterile age, or ages of weak reproductive energy characterized by absolute sterility and by morbid production, whether abortive, premature, or mature. At present we only consider the production of mature children, and we find the unnatural intensity of fertility in the young shown by absolutely large number, that is, above ten; while in the elderly it is shown by rapidity of births or intensity of fertility, so long as it lasts; and we may here remark that it has been elsewhere proved that for such women as begin childbearing late in life, there is a prolongation of the period of fertility beyond the average age of ceasing to bear, not a prolongation, as estimated from beginning to end, of actual childbearing.

That the fertile younger are more fertile than the fertile older is shown by the following table of data derived from St. George's-in-the-East. That the younger fertile have a longer perseverance in

TABLE XVII.

Showing the Fertility of Mothers Married at Different Ages.

Years elapsed since birth of first child.	Average number of children to each marriage formed at ages—			
	16-20	21-25	26-30	31-35

40	10·85	8·24	5·00	4·00

fertility than the fertile older is shown by Table XVIII., derived from my work on Fecundity. That the unnatural intensity of fertility in women bearing large families begins with the commencement of childbearing is shown by Table XIX. from Ansell, which demonstrates the rapidity, only up to the birth of the third child, in families of various numbers. Up to the third birth the rapidity is twice as great in families of sixteen or more as in families not above three, and it is easily counted that while the small families came slowly, and the excessive families quickly, the families from seven

greater intensity than that of women married and beginning to childbear at the best ages. (See Table XX.) The table reads thus: To take the second row of figures—Fertile women five years married and under ten have, if they are now from fifteen to nineteen years of age, 2.5 children; if now from twenty to twenty-four years of age, 3.19 children; if now from twenty-five to twenty-nine years of age, 3.75 children and so on.

Multiparity is a term already well recognized as implying that the subjects of it have had two or more pregnancies and births; but a woman may

to twelve came nearly at the average rate of one every eighteen months. That the unnatural rapidity of childbearing in excessive families continues throughout childbearing life is shown clearly by Tables IV. and V. In my table the quickest childbearing is every ten months, the family being nineteen in number. In Ansell's table the quickest is every fifteen months, the family being eighteen.

Lastly we show, by a table framed from the Edinburgh and Glasgow data, that the wives beginning fertility at advanced periods of life have an unnatural intensity of fertility while it lasts, a

bring forth two or more children at once, and to this condition we apply the term pluriparity. The most common degree of pluriparity is the production of twins, these occurring about once in every eighty pregnancies. Triplets and higher numbers are very much rarer, and the rarity increases with the number.

Chiari, Braun, and Spaeth have given good evidence that abortions are comparatively more frequent in plural than in ordinary pregnancies. McOlintock, founding on large experience, shows that hydramnios is also common. Acephalous monsters are found only in plural pregnancies. Monstros-

ities of all kinds are commoner in plural than in ordinary pregnancies. There are more dead-born children in plural pregnancies. The children born alive in plural pregnancies are more difficult to rear. "The proportion," says Ansell, "of infants that are stillborn or die soon after birth is, in the case of males nearly five times, and in the case of females nearly four times, greater in multiple than in single births."

Subsequently we shall adduce evidence that pluriparity is specially associated with idiocy and imbecility of the children, and that it specially affects the sterile ages, or ages of weakness of reproduction. Excessive family, that is, above ten in number, specially affects the same ages and is dangerous to the lives and injurious to the health of both mothers and children. Both have therefore an alliance with sterility.

In a case of quintuplets the mother's age was forty and the pregnancy the tenth. In 7 cases of quadruplets the age of the mother was given in 6, and the mean is twenty-seven; the number of pregnancy was given in 6, and the mean is nearly three. The ages were nineteen and twenty with first pregnancies; twenty-five with third pregnancy; thirty with number of pregnancy not stated; thirty-two with a fifth pregnancy, and thirty-five with a fourth pregnancy. In one case of second pregnancy the age of the mother was not given. From a great variety of sources I have collected 43 cases

leads us to regard twinning in the human species as a departure from the physiological rule, and therefore injurious to all concerned. 5. When we pass from twins to triplets and quadruplets, everything we know regarding these latter gives support to the general conclusions in question."

Besides these accumulated dangers and disasters to the children produced in pleural pregnancies we know that pleural pregnancy is dangerous and disastrous to the mothers. The trivial and the graver disorders of pregnancy are more common in pluriparous than in uniparous women, and the disasters and deaths in childbirth and in childbed are also more numerous in the pluriparous than in the uniparous. Nothing can be better demonstrated than that woman is naturally or normally uniparous, and that pluriparity is an unnatural or abnormal condition connected with sterility by being observed in the sterile ages, or ages of weakness, or imperfection of reproductive power. It does not imply the desirable productiveness of health and vigor, but the reverse.

Pluriparity in a population, then, is not an indication that its social condition is as it should be. It shows, according to its amount, that marriages take place too early or too late in life; and it may be predicated of such a population that it has a correspondingly large maternal and infantile mortality, and that the reared children are not of the finest. While woman is normally or physiologi-

Showing the Number of Pregnancy in Forty-one Cases of Triplets.

Number of pregnancy.....	1	2	3	4	5	6	7	8	10	11	12
Number of triplets.....	8	8	12	2	2	2	3	1	1	1	1

of triplets (and of these I give in the subjoined tables some account). (See Table XXI.) In 40 cases the age of the mother is given, and the mean is thirty. In 41 cases the number of the pregnancy is given, and the mean is four. (See Table XXII.) It is naturally expected that our best evidence should be derived from twins, but while this is really so we have, even in these cases, to deplore the inadequacy of the data in point of number. I have not at present sufficient time at my disposal to enter into the details of the production of twins, and for these I refer you to my work on Fecundity. It is there shown that the frequency of twins increases with the age of the mother and with the number of the pregnancy, the very early ages of the mothers and the first pregnancy forming exceptions to the rule.

In a paper by Arthur Mitchell, published in the *Medical Times and Gazette* (Nov. 15th, 1862), he shows that twins are peculiarly liable to be imbeciles or idiots. The conclusions of Mitchell's paper are so pertinent to the present subject that I quote them here at length. "1. Among imbeciles and idiots a much larger proportion is actually found to be twin-born than among the general community. 2. Among the relatives of imbeciles and idiots twinning is also found to be very frequent. 3. In families, when twinning is frequent, bodily deformities [of defect and of excess] likewise occur with frequency. 4. The whole history of twin births is exceptional, indicates imperfect development and feeble organization in the product, and

cally uniparous, like the mare and cow, many of the other domestic animals are normally or physiologically pluriparous, as the dog, the rabbit, and the sow; and the fertility of most birds is a sort of pluriparity.

In the uniparous animals pluriparity is rare in various degrees in the different kinds; but the extreme rarity in some, as in the mare, may to some extent depend on the circumstance that, in general, only the finest specimens at the most suitable ages are allowed to exhibit their fertility. Little, indeed, is known about them with the exactness desiderated with a view to comparison with woman. Yet we may safely assert that, among breeders of horses and cattle, the production of twins is, with a view to their interest in both mother and offspring, not looked upon with favor. In the sheep there is such a frequency of twins, and even of triplets, that there may be some hesitation in classing it with uniparous mammals.

In the pluriparous animals, on the other hand, uniparity is uncommon, and pauciparity is an indication of reproductive weakness or imperfection, while a just degree of pluriparity is natural or physiological. It is remarked, says Spencer, by Buffon that when a sow of less than a year old has young, the number of the litter is small, and its members are feeble and even imperfect.

The domestic hen, in its fertile career, admirably illustrates the rise and decline of pluriparity, and the variations are in accord with the great law of age which holds good in women and in all

living beings. Its first and its last productions are small in size, and are believed to be peculiarly liable to be addled or without yolk, or to be otherwise incapable of being hatched. In its first year, according to Geyelin, it produces only 15 or 20 eggs; in its second, 100 or more, up to 120; in its third year, from 120 to 135, and here the climax of fertility is reached; in its fourth year it produces from 100 to 115; in its fifth, from 60 to 80; in its sixth, from 50 to 60; in its seventh, from 35 to 40; in its eighth, from 15 to 20; in its ninth, from 1 to 10. The fertility rises quickly to its summum in the third year of life, and more slowly fades to its disappearance in the tenth year of life.

In like manner the bitch and pig begin their fertile course with a small number, which year by year rapidly increases; and after a few years, whose number I cannot give, again decreases, till fecundity disappears, the last production being often a premature or a dead foetus. The pluriparous animal has its best young when its progeny is most numerous. The best young may be so described, as in pups, on account of their intelligence, docility, or special talents; or they may, as in a litter of pigs, be best because they are large and easily made to grow to great bulk or weight. In the case of the bitch, it is impossible to reduce to an exact statement the value of pluriparity, but it is no doubt, very great; and while it is the case that when most in number are produced, there is also most in weight; the statement of weight of the pups gives no idea of their value. In a litter of pigs, the value of pluriparity is a simple matter, being estimated almost entirely by weight and capability of rapid growth; and both may be very well stated in figures.

The uniparous mare has a foal which may be valued partly for bulk, especially if it is to do rough, heavy work; but the bulk of a foal bred in the racing stud is a matter of comparatively little moment; and I daresay all will agree that the nobler the breed of horses, or the higher the qualities expected in them, so is bulk in the foal of less and less importance, and so also is pluriparity less and less desirable.

We have already used estimates of weight and length of single children as indications of fertility in woman; and if weight and length of twins were a test of paramount import, then twinning would, correspondingly, connote fertility, as 12 lb. exceeds 6½ lb. or 7 lb. But there are higher qualities than the combined weights and lengths, and it is these higher qualities that are deficient in twins. Weight and length are valued merely as indications of general health and full development of individuals, not of twins.

Pluriparity in uniparous animals is rare, and for its study great accumulation of instances is required; and knowledge regarding it in these animals is tardily gained. Pluriparity in some common domestic animals is an every-day matter; and without any deliberate study its variations strike even the obtuse, a class often specially sensible of the pecuniary advantages of the higher degrees of pluriparity. It is the striking characters and advantages of high degrees of pluriparity in pluriparous animals that have led to the general adoption of the erroneous opinion that pluriparity even in the uniparous animals, as in woman, is an unqualified sign of fertility. In pluriparous animals, especially in the common hen, the quick rise and more gradual decline of fecundity is plainly observed, the climax in the hen, as in other pluriparous animals, being marked by the highest number of annual production or in a single brood or litter. In woman there is the same kind of variation, but in her it is a decline from occasional

pluriparity to the production with due intervals of the best kind of single births; and the rise is back again to occasional pluriparity and hurry of births one after another.

In the common hen the rise to the climax occupies three years of life, and the more gradual decline occupies six years, according to Geyelin's data, already given. In woman the decline to the lowest, if we count roughly, from fifteen to twenty-five years of age, occupies ten years and the more gradual rise, from twenty-five to forty-five, occupies twenty years. In the hen the rise is from 15 to 135, and the decline from 135 to 1. In woman the decline is from about 1.02 to 1, and the rise again to about 1.02. There can be little doubt that a similar rise and fall, or fall and rise, are to be found in the history of the fertility of other living things. The curve of this climax and anti-climax is not a part of a circle. Dr. Houth, in a valuable paper on "Procreative Power," published in the *London Journal of Medicine* for 1850, describes this curve, representing what he calls the inclination of procreative power, and thinks the circle is perhaps the nearest that could be selected; but the circle cannot be made to represent the figures on which he relies. He makes the age of greatest fecundity in woman twenty-six; and the climax and anti-climax may be partially indicated by the following figures, which he gives:—At fifteen years of age the figure is 22; at twenty it is 82; at twenty-six it is 100; at thirty it is 92; at thirty-five it is 74; at forty it is 54; at forty-five it is 39.

In leaving the subject of twins, it is natural to refer to malformations and monstrosities as showing weakness or disorder of the reproductive powers, but on this point I have no good detailed evidence to adduce meantime. Yet it is well known that a great body of opinion is in favor of the view, and there are many facts pointing in the same direction. In the course of these Lectures I have frequently mentioned such opinions and facts, but the subject is well worthy of special study. Here I would only refer to the frequent combinations of idiocy and malformation, of idiocy and twins, of idiocy and premature or post-mature maternity, of malformation and twins, of interbreeding and malformation, of interbreeding and sterility, as combining to form an argument that may, if worked out, be found to be conclusive on this question.

Experiments in producing malformations and monstrosities in the common fowl have been very fruitful in results, and demand caution in judgment as to the potency of such influences as age of the mother. Especially interesting in this view is the recent discovery of Dareste that mere delay of incubation, in the case of the eggs of the common fowl, is a cause of malformation in the chick.

Excluding some remarks as to the influence of marriage in causing sterility in woman, we have shown chiefly the influence of age in its production. Marking out by statistical evidence certain ages as peculiarly affected with sterility, we find at these same ages, in a proportion above the average, excessive families, pluriparity, weakly or idiotic children, etc., and not only in exaggerated proportion, but combined one with another. It is therefore reasonable to describe the sterile ages as ages of imperfect reproduction, and to associate or identify with sterility the conditions of excessive production, pluriparity, etc., which are demonstrated to have alliance with it. In other words, sterility, excessive families, and pluriparity are alternatives one of another, and almost certainly own the same general causes.

I know no cause of sterility or of its allies, excessive production, pluriparity, abortion, etc., that can be compared with age in extent and power.

In discussing the cure of sterility, I shall allude to various minor causes which may operate in individual cases, but have no extensive influence. But there are causes which probably have a great place in the production of this condition whose action is only believed, not demonstrated. Such are bad general health, cold, and heat. The influence of bad general health is well observed in plants, but I know no good evidence of it in woman other than the testimony of medical practitioners. The influence of cold and of heat on sterility has been much studied, and attempts have been made to get additional light on the matter by collecting observations of their influence on the age of commencement and cessation of menstruation. The subject divides itself into two portions: first, the influence of cold and heat on women breeding in their native lands; second, the same influence as exerted on women born in cold climates and transported to hot, or born in hot climates and transported to cold. But the data obtained are, in my opinion, quite insufficient for any reasoning being securely based. The hearsay evidence also requires scrutiny. We often hear, for example, of a girl, say of eleven, bearing a child in India, and this is held as proof of early fecundity there. We rarely hear of the same occurrence in this country; and the reason of this alleged greater frequency in India may be not early fecundity there, but earlier exposure of a large number of girls to the risk of becoming pregnant.

There are several important subjects, more or less closely bearing on our inquiry, which I pass by with mention only. Among these is the influence of cold and heat on the commencement and stoppage of menstruation, an influence regarding which it is scarcely, by the statistical evidence, made probable that cold retards the appearance and hastens the stoppage, though many considerations support this view. Another is the generally accredited influence of nursing in delaying the return of menstruation and the recurrence of pregnancy. Regarding these matters Robertson has made valuable remarks, and collected many, though insufficient, observations. The great subject of interbreeding in its production of sterility I also pass over. The evidence regarding it is very bulky, and requires most careful sifting. In plants and animals the demonstration of this injurious influence of interbreeding in producing imperfection of offspring and sterility is copiously illustrated, and may be said to be well made out; but it is not so in the case of man. Yet, in the case of man, there is a most extensive, though not universal, consensus of intelligent opinion that interbreeding has the same general influence as in plants and animals, and to the entertainment of this view the strong analogy of plants and animals lends powerful encouragement. The injurious influence in man, indeed, probably acts after birth, for there is accumulating evidence that peculiar diseases, specially of the eyes, affect, by preference, the offspring of near relations.

"The evil consequences," says Darwin, "of long-continued close interbreeding are not so easily recognized as the good effects from crossing, for the deterioration is gradual. Nevertheless, it is the general opinion of those who have had most experience, especially with animals which propagate quickly that evil does inevitably follow sooner or later, but at different rates with different animals. No doubt a false belief may unduly prevail, like a superstition; yet it is difficult to suppose that so many acute and original observers have all been deceived at the expense of much cost and trouble. The loss of fertility, when it occurs, seems never to be absolute, but only

relative, to animals of the same blood; so that this sterility is, to a certain extent, analogous with that of self-impotent plants which cannot be fertilized by their own pollen, but are perfectly fertile with pollen of any other plant of the same species. The fact of infertility of this peculiar nature being one of the results of long-continued interbreeding, shows that interbreeding does not act merely by combining and augmenting various morbid tendencies common to both parents; for animals with such tendencies, if not at the time actually ill, can generally propagate their kind. Although offspring descended from the nearest blood relations are not necessarily deteriorated in structure, yet some authors believe that they are eminently liable to malformations; and this is not improbable, as everything which lessens the vital powers acts in this manner. Instances of this kind have been recorded in the case of pigs, bloodhounds, and some other animals." "In the case of man," he elsewhere remarks, "the question whether evil follows from close interbreeding will probably never be answered by direct evidence, as he propagates his kind so slowly, and cannot be subjected to experiment; but the almost universal practice of all races at all times of avoiding closely related marriages is an argument of considerable weight, and whatever conclusion we arrive at in regard to the higher animals may be safely extended to man."

Leaving several minor or little known causes of sterility to be mentioned in the next Lecture, I now turn to other matters in its history which throw light on its theory, and there are two worthy of great consideration. These are the well-known association of dysmenorrhœa with sterility, and the state of sexual appetite and sexual pleasure in sterile women.

Menstruation, when natural or healthy, is attended with no pain, and with little or no disturbance of general health. When there is pain or considerable disturbance of health, the condition is called dysmenorrhœa, and it is plain that the term covers a wide and ill-defined field of disorder and disease. It is with dysmenorrhœa, as thus vaguely defined, that sterility is prevalently believed to be very frequently associated; and there can, in my opinion, be no doubt of the truth of the general belief.

There is a kind of dysmenorrhœa, regarding which I would enter into more details. It is called spasmodic, being regarded as a neurosis characterized by painful uterine spasms, which may be described as having no known object in view. It is often called mechanical or obstructive, terms implying a theory of its cause and implying also that the spasms are, so to speak, intended for the expulsion of the menstrual fluid accumulating in the uterine cavity and distending it. There is no good evidence of the mechanical obstruction, nor of the accumulation of menstrual fluid, nor of the dilatation of the uterine cavity, nor of the use of the painful uterine contractions; and as all admit the presence of these contractions or painful spasms, I shall call this kind of dysmenorrhœa spasmodic. It is a kind of dysmenorrhœa that is gradually, and I think justly, restricting to itself alone this term—the only real, positive, recognizable uterine dysmenorrhœa, or the dysmenorrhœa proper.

It is of this dysmenorrhœa proper that I am now to speak, and it is known by the following characters. It may occur at any time during the flow of menses, sometimes even before it begins; and, in cases of amenorrhœa, it may occur at the time of the menstrual molimen. In the very great majority of cases it occurs on the first or second day of the flow, and it is generally severer when

the flow is scanty than when it is copious. The pain is constant or in pangs; and the pangs may be more or less distinct—in other words, the intermissions of the pain may be more or less complete. The frequency of the pangs varies, five to ten in an hour being common. The pain is rarely accompanied by bearing down, strangury, or tenesmus. It varies in severity, rising occasionally to the intensest agony, with cold sweats, vomiting, and other symptoms of prostration or collapse. Suffering from it the patient rolls about and groans, and the restlessness is not that of fever, but of griping pain. It may last only a few minutes, but generally it goes on for hours, the number of hours rarely exceeding four or five. It rarely returns during the current menstrual period. It is generally aggravated by marriage. In women who suffer from this disease there is a super-sensitive condition of the interior of the body of the uterus, and, I think, especially of the internal os uteri, this condition being tested by the contact of a uterine probe or sound.

In making inquiries as to the connection of this dysmenorrhœa proper with sterility, I have frequently, but not always, satisfied myself of the presence of all of these characters. Particularly, I have not classed with this dysmenorrhœa any case in which the severe pain lasted more than a day. In all inquiries as to pain, there is, owing to the indefiniteness of language and the tendency of patients to exaggerate or make light of their troubles, extreme insecurity of statistical statements. I have tried to avoid being misled in 332 cases which I have, during the last five years, taken down in my notes. These 332 cases were all absolutely sterile—that is, all women who had had an abortion or a child are excluded. Of these 332 married women 159 suffered from spasmodic dysmenorrhœa, or nearly half. It is a most grave fault in my argument that I unfortunately cannot give the frequency of dysmenorrhœa among the fertile. But I can meantime only declare the importance of the omission and express my belief, in accord with universal professional opinion, that among the fertile dysmenorrhœa is comparatively uncommon. The connection of a neurosis of this kind with sterility cannot be unimportant, and I cannot leave the subject without expressing my belief of the association of it with abortion and miscarriage also.

Other mutually allied neurotic conditions demand full consideration—namely, sexual appetite or desire and sexual pleasure or satisfaction of the appetite by coitus. In investigating the matter great difficulties are met with from the delicate nature of the inquiry, the difficulty of making sure that the patient understands clearly what is the question to be answered, and the impossibility of finding words of well-defined meaning, or of the same meaning in different mouths. But these difficulties are not insuperable, and error is lessened by relying on a large number of concurring observations.

Sexual desire and pleasure have to be considered separately, because, though they are naturally found combined in the same case, they are far from being invariably so. A woman, with healthy sexual organs, may have sexual desire and no pleasure, or even the reverse, and she may have no desire and yet have pleasure. Although pregnancy and childbearing are natural consequences of sexual desire and pleasure, there is little or no connection between the latter and the wish to bear children. The desire for offspring may be intense, while there is neither desire nor pleasure, and the desire to avoid pregnancy may be intense while there is desire and pleasure. Desire and pleasure may be excessive, furious, overpowering, without bringing the female into the class of maniacs.

They may be temporary, healthy, and moderate; they may be absent or null. Instead of sexual desire there may be sexual aversion; and instead of sexual pleasure there may be only feelings of disturbance or pain. Instead of sexual desire there may be intense sexual antipathy, and instead of sexual pleasure there may be severe suffering, even agony in coitus.

The variations of desire are chiefly on the positive side, greater or less. Desire may be absent. From the zero or indifferent condition there is, however, not rarely observed a rise into aversion or antipathy, and this, in married women, without any feeling regarding the husband other than affectionate. It is well known that desire may be fostered at special times by various stimulants of passion; but, apart from such occasions, it may be increased or diminished or annihilated. This is a general belief, and I have frequently had spontaneous testimony of individuals to the same effect. The influence of society and its amusements, of diet, of special kinds of reading, of association with males, is well known and recognized in the increase of sexual desire; and the influence of the opposite conditions, of a truly ascetic life, is equally certain. Desire may, during the child-bearing period of life, undergo great changes without any apparent cause; at one time, and it may be for years, being positive, at another time absent or negative.

Sexual pleasure must not be regarded as in all respects like sexual desire, and requires separate description. Its variations are chiefly on the positive side. It may be absent. Its variations on the negative side are, however, most remarkable. There may be slight or very great suffering, or the intensest agony; and this is often accompanied by more or less active involuntary local sphincteric resistance to penetration, called vaginismus. But the words pain and agony are here used in a quite extraordinary and misleading way. There is no pain, such as that of the infliction of a wound or contusion, or that of toothache or neuralgia. There may indeed be, in cases of diseased sexual organs, common pain of the kinds mentioned, caused by sexual congress, but of such pain we are not here speaking.

All kinds of pain or discomfort in coitus are often, nowadays, classed as dyspareunia, but I think the word may be well restricted to the condition I am describing; or the condition may be called simple dyspareunia, and there is no common pain in simple dyspareunia. It has an analogue in disgust, but dyspareunia rises to far higher degrees than disgust. As sexual pleasure rises in intensity above all other kinds of pleasure, so dyspareunia reaches degrees exceeding those of the intensest disgust. The disgust of a child is often painfully intense, its resistance to tasting and swallowing involuntary and powerful, and often followed by vomiting the matter whether tasted or not, and as all this is not common pain in tasting and swallowing, so dyspareunia is not pain in sexual connection. Sexual pleasure and dyspareunia differ from gustatory pleasure and disgust in this, that while the former are one in kind and in all degrees excited by the same cause, the latter are various in kind, and elicited by different substances in each case. Pleasure, then, may vary from the intensest to mere indifference; and simple dyspareunia may rise from mere indifference to the highest degree, with sphincteric resistance to penetration, opisthotonos, and a state almost of insensibility.

Pleasure is probably not directly increased by the causes of increase of desire, but the increase of desire is probably a cause of increase of pleasure, as hunger enhances the pleasures of taste. Pleasure

is increased by continence and diminished, or annulled, or converted into slight dyspareunia by over-indulgence. Sexual pleasure may vary without apparent cause, disappearing for short periods or for years, and reappearing with the same appearance of caprice. Pleasure is frequently absent at marriage, and gradually developed during the continuance of that state. If it is slight at marriage, then coitus will be painful, the common and not simple dyspareunic pain overpowering the pleasure and preventing it.

Describing the lower animals in this respect, we guess by aid of analogy, but the analogy is so strong as to endow the guess with a high degree of assurance, reaching nearly to certainty. We may be sure that animals, generally, feel sexual desire, and that this sexual desire occurs normally or naturally only in connection with fecundity. In many domestic, or otherwise well-known, animals there is sexual desire only in the rutting season, and at other times not only an absence of sexual desire, but a positive sexual antipathy. A bitch not in heat will angrily resist any attempt at sexual approach by the male, while quite ready for any other kind of play. Of sexual pleasure in female lower animals we know very little, but we may be sure it exists. Of its existence in males we have abundant evidence, and we may thence argue that it exists in females. Nothing is commoner in dogs than what may be called masturbation. This kind of sexual pleasure is generally believed to be increased by confinement, and the evidence afforded by zoological collections is held to be good.

I know nothing regarding the connection of sexual pleasure in animals with fertility or sterility, but we have the testimony of Darwin to the presence, in animals that are confined, of sexual desire, sometimes in excessive degree; sexual indulgence being held as evidence of sexual desire; and the sexual excess is often connected with sterility. "Monkeys" says he, in the Nine-Year Report from the Zoological Gardens, "are stated to unite most freely, but during this period, though many individuals were kept, there were only seven births." Elsewhere he says, that "although many of the felidæ breed readily in the Zoological Gardens, yet conception by no means always follows union. In the Nine-Year Report, various species are specified which were observed to couple seventy-three times, and no doubt this must have passed many times unnoticed; yet from the seventy-three unions only fifteen births ensued." In many animals under confinement there is no coupling, and this may be assumed to indicate absence of desire in female as well as male.

It is an almost universal opinion that in woman desire and pleasure are in every case present, or are in every case called forth by the proper stimulants. The opinion is founded on experience, and it is, no doubt, nearly true; but the exceptions to the rule are numerous and important. It is also a popular opinion that desire and pleasure are essential elements in fecundity, and in cases of rape followed by pregnancy, that consequence has been made ground of defence against the charge. Great authors, among whom is Ambrose Paré, recommend the excitement by dalliance of great desire, as a remedy of sterility.

I think it is very nearly certain that desire and pleasure in due or moderate degree are very important aids to, or predisposing causes of, fecundity, not on account of their own proper attractiveness, but on account of some connection between them and the perfection of other parts of the complicated proceedings which result in fecundation. But this is only a firmly held opinion, for I can give no conclusive evidence or proof of it; and this absence of proof diminishes greatly the value of my

observations on the absence of desire and pleasure in the sterile. The want most acutely felt here is a knowledge of the state, in this respect, of the fertile. In producing evidence as to the sterile, I shall assume that sexual desire and pleasure are very rarely absent in the fertile. Excess of sexual desire is probably unfavorable to fertility. It is recognized chiefly by excessive indulgence in sexual pleasure, and is observed in the weak and ill-conditioned, in imbeciles and idiots, as it is also in animals under confinement. Excessive indulgence in sexual pleasure is also probably unfavorable to fertility, or a cause of sterility; and it probably is specially influential in the young, as it may also be in prostitutes. In these circumstances the births of females are, on good grounds, believed to be far above the ordinary average, in proportion to males.

Masturbation in females is an unnatural and generally excessive indulgence in artificial sexual pleasure. It has always appeared to me to affect especially children and young women of weak mind. I have often been struck by the smallness or imperfect development of the external parts in young women who masturbate, and I have not rarely observed what appeared excessively high development of sexual desire in women who had imperfection or absence of internal genital organs. In one, dissection revealed the presence of ovaries and Fallopian tubes only. Some confirmation of these views may be found in cases such as that of Campbell,¹ in which a woman addicted to masturbation had never menstruated, and had imperfectly developed genital organs; she had, however, also a dermoid cyst of the ovary. Arran² has a case, of what he describes as frightful excess of masturbation, in a young woman dying of phthisis, whose uterus and appendages were found to be very imperfectly developed. Kussmaul³ mentions the concurrence of masturbation and nymphomania with imperfect development of the uterus and the genital organs; and Joulin⁴ refers to a case of Vaddington's where absence of uterus and exaggerated sexual appetite were combined.

Entire absence of desire and pleasure, or of one of them, or the presence of intense sexual antipathy and dyspareunia are not necessarily causes of sterility. It is not at all rare for women to be pregnant and bear healthy children who aver in the distinctest manner not only absence of desire and pleasure, but presence of the opposite conditions. But the following statistics make it highly probable that absence of desire and pleasure and the presence of their opposites are powerful influences favorable to sterility. The statistics do not indicate what was occasionally found—namely, that desire was present while pleasure was absent; or, in other cases, that desire was absent while pleasure was present. The cases observed were all in women absolutely sterile, of whom the great majority consulted me regarding the sterility. Among 191 sterile wives desire was absent in 39, or in about 1 in 4. Among 196 of the same sterile wives pleasure was absent in 62, or in about 1 in 3. The figures show that many sterile wives had desire but no pleasure. They do not show, what nevertheless is true, that some had pleasure who had no desire. (See Table XXIII.)

I have a strong impression, derived from all I know and have observed, which I may express theoretically, that while in healthy normal women there is abundance of sexual or reproductive energy for fertility and all its accompaniments,

⁴ Accouchements, p. 138.

in many sterile, or relatively sterile, women, there is deficiency which may be exhibited in one or another, or in all the ordinary evidences of reproductive energy, and that excess or deficiency in one department may be associated with deficiency or excess in another. It would seem that in women of deficient reproductive energy, excess in one department might be compensated by deficiency in another, and *vice versa*, there being only a limited store of the original energy. In illustration, a remarkable class of cases may be cited, which I shall sufficiently describe by stating generally the chief points in one:—A robust healthy woman is married at eighteen; she bears three

clear fluid. Its weight varies much within the limits of health, according to the ratio between the dissolved solids and the water; a specific gravity of 1020 may be taken as the average. Its reaction is decidedly acid, but the amount of its acidity depends on the time of its excretion, especially in relation to food; at times the urine may, for a short period, become neutral, or even alkaline. Healthy human urine consists of water, holding in solution both organic and inorganic principles; the former are, urea, uric, and hippuric acid; the latter, chlorides of different metals, especially sodium, and phosphates of sodium, magnesium, and calcium.

TABLE XXIII.

Case-book Table of Desire and Pleasure in Sterile Women.

Age at marriage.	Number.	Desire.			Pleasure.		
		Present.	Absent.	No note.	Present.	Absent.	No note.
Fifteen to nineteen.....	59	18	4	37	15	8	36
Twenty to twenty-four.....	220	78	18	124	69	27	124
Twenty-five to twenty-nine	134	35	12	87	31	18	85
Thirty to thirty-four.....	59	16	3	40	14	5	40
Thirty-five to thirty-nine...	23	3	1	19	3	3	17
Forty to forty-five.....	9	2	1	6	2	1	6

children and has four miscarriages before she has passed twenty-three years of age. Up to the birth of her last child, and for five years subsequently, she experiences no sexual desire, and has no pleasure. Five years after her last pregnancy she almost suddenly comes to have intense desire and pleasure, but remains sterile for four additional years before she seeks a cure of her sterility. Fertility present, while desire and pleasure are absent: sterility present, while desire and pleasure are present.

Mumleian Lectures

ON

URIC ACID: ITS PHYSIOLOGY AND ITS RELATION TO RENAL CALCULI AND GRAVEL.

Delivered before the Royal College of Physicians,

By A. B. GARROD, M.D., F.R.S., F.R.C.P., etc.,

Consulting Physician to King's College Hospital.

LECTURE II.

MR. PRESIDENT AND GENTLEMEN—Having stated in the former lecture my views as to the production of uric acid in the animal economy, reserving only certain points to be discussed as we proceed, and having shown that the difficulties which beset the theory that the kidneys are nothing more than the strainers-off of this principle are extremely great, if not insuperable, and that therefore there is no little probability that uric acid is a true product of the renal organs themselves, I will direct attention to the subject of human urine, and the alterations which it undergoes under certain conditions, which lead to the production of those morbid formations commonly called gravel and calculi.

Healthy urine, omitting the trace of mucoid matter contained in it, which consists of the débris or washings from the mucous membrane of the urinary tract, it is well known, is a perfectly

It is to uric acid that we must chiefly direct attention; and I must endeavor to show (1) in what state of chemical combination it exists in the urine; (2) why it is held in solution in an acid fluid; (3) what are the causes which lead to its precipitation from the urine; and (4) what are the different shapes which it assumes when it is thus precipitated from its state of solution.

1. At the present day I believe it may be asserted that uric acid, when in solution, is combined chiefly with sodium, but that there are also varying quantities of other bases present, depending on the amounts of different salts contained in the urine. I have already shown that when urate of ammonium is dissolved in blood serum in which the soda salts are present, it is converted into urate of sodium; and, bearing this fact in mind, we can explain the discrepancies which are found in the different analyses of urate deposits, both in health and disease. I may, however, say that the deposit which until recently was commonly called lithate of ammonia is composed almost entirely, in healthy urine, of urate of sodium. If, however, the urine at any time becomes ammoniacal from the decomposition of the contained urea, then the uric acid, meeting with a large excess of the new-formed base, gets deposited as urate of ammonium, a salt which is very insoluble.

2. The next point to be considered is the reason of its existence as urate of sodium in a fluid having such a well-marked acid reaction as healthy urine. This fact was for a long time difficult of explanation; but Liebig showed that if to a warm solution of the common phosphate of sodium, which has an alkaline reaction, uric acid be added till it no longer dissolves, the solution becomes strongly acid, and there is contained in it urate of sodium and the acid phosphate of sodium, which latter salt exhibits a full acid reaction, but does not possess the power of precipitating the uric acid. This phenomenon solely depends on the tribasic character of phosphoric acid, which allows of a solution of phosphates, which reddens litmus powerfully without containing any free acid.

3. When, however, the least trace of a free acid, even acetic, exists in the urine, the whole of the uric acid is rapidly precipitated; a fact of consid-

erable importance in the study of diseased conditions of the urinary excretion. If our attention is directed to the subject, we see, almost daily, that, when urine is kept for a time, perhaps only a few hours, the uric acid, which at first was in complete solution, becomes gradually deposited in the crystalline form—a change due to the generation of a free acid in the urine by the occurrence of what is called the acid fermentation.

4. Our last point is to ascertain what shape the uric acid assumes when it becomes insoluble, and is precipitated from the urine. It may be thrown down either in combination with a base—that is, in the form of a urate, or as free uric acid. When as a urate, it is often from simple concentration, or from the presence of too small a quantity of water in the urine, and it seldom happens that such deposition takes place in the urinary organs themselves unless there is a something present, such as a foreign body or the nucleus of a calculus, which greatly facilitates it. When, however, such urine is removed from the body and cooled down to the temperature of the air, more especially in cold weather, the appearance of turbidity is extremely common, and often becomes, though most unnecessarily, a source of great mental disquiet to patients. When the urine, either concentrated or not, becomes abnormally acid, it at first causes the urate existing in it to be less soluble, but soon afterwards the acid itself is separated and deposited in the crystalline condition, forming what is commonly known by the name of Cayenne pepper gravel. Let us take what may be looked upon as pure uric acid; dissolve it in boiling water, and then allow it to cool and crystallize; it will be found in oblong tabular crystals, which are both homogeneous and transparent. When uric acid crystallizes out from urine, it is more or less colored, from yellow to brown, and in the form of thin rhomboidal prisms, showing that there must exist in the urine something which causes an alteration not merely in the color, but also in the crystalline form.

Dr. Ord, in his work on "The Influence of Colloids upon Crystalline Form and Cohesion," gives the results which he has obtained from the crystallization of uric acid under the influence of urea, coloring matters, mucus, albumen, cane and grape sugar, gum arabic, starch, gelatine, and glycogen. It appears to me that the researches of Dr. Ord and Mr. Rainey are not only valuable, but also seem to throw a ray of light—dim, it is true, at present—upon those phenomena which, as it were, connect true chemical changes with those we are accustomed to look upon as due to the agency of life.

The result of our inquiries, as far as they go, may be summed up in a few words. Perfectly healthy urine should show no appreciable deposit; when, however, it becomes concentrated from deficiency of the watery excretion, then the uric acid is thrown down in the form of a urate. This may occasionally occur within the body, but far more frequently after the urine has been voided; sometimes, however, this change ensues so rapidly that the urine is erroneously supposed to have been passed in that condition. The presence of a solid body in any part of the urinary tract favors deposition very much, and hence urine which would otherwise remain clear may yield a deposit to any substance previously present in the same tract, and may thus add considerably to an already existing calculus. The appearance of the numerous layers so frequently seen around a central nucleus, both in renal and vesical calculi, is thus easily explained. When, however, the urine becomes further altered in composition—if, for example, a free acid is either excreted with the urine or rapidly generated

in it through the setting up of the lactic fermentation, the uric acid becomes liberated from its state of combination, and, in a form more or less altered by the presence of colloid matters, is deposited on a previously existing calculus, or is passed as separate rhomboidal crystals or in aggregated masses, constituting gravel or sand. I should feel disposed to confine the name of "sand" or "gravel" exclusively to such deposits which, I believe, seldom form the nucleus or become the starting-point of any calculus. I may add, that urine possessing these characters is frequently voided for months and years without the occurrence of any appreciable inconvenience to the patient. It is true that a calculus may be augmented by contact with such a urine; but, as I have said, it seldom originates in this way.

According to this view, which I feel inclined to adopt, gravel or sand consists of uric acid previously in a state of solution, which has become precipitated by the occurrence of some change in the urinary excretion.

Some individuals pass a larger daily quantity of uric acid than others; but, at the same time, those who pass the largest quantity may have a urine little disposed to deposit the principle; and it will be found, as a result of experience, that changes in the urinary excretion, leading to the crystallization of its contained uric acid, are much more potent factors in the production of sand or gravel than the mere quantity of this acid which is eliminated. If there is a simultaneous occurrence of the two conditions—that is, of increased quantity of the acid and altered state of the urine—this facilitates still more the production of the morbid appearances.

We have already assumed that the excretion of reptiles and birds consists of uric acid, united with ammonia, and it is usually regarded as being urate of ammonium; under these circumstances it would be expected to behave like such a salt when acted upon by different reagents. We will now see whether it does so.

Let us take two graduated tubes, divided into one hundred parts, and put into one the ordinary salt, the acid urate of ammonium, so as to stand to the height of five divisions. Into the second tube, let us put the dry and powdered white excretion of some large reptile, such as the python or boa, and fill each tube with a one per cent. solution of carbonate of lithium, up to the one hundredth division. Let us place the tubes upright in a stand, and shake them from time to time. On examining the contents of the first tube, after the lapse of hours, days, or even weeks, no change will be perceptible; the artificial urate will still occupy the same space, five divisions, and no more. In the second tube, very different appearances will be exhibited—a change occurring to some extent even after a few minutes, with some slight puffing and some little translucency of the substance; while, in the course of an hour or two, the swelling will become very great, and go on increasing for twenty-four hours or more, till at last a solid magma will be formed, occupying eighty to ninety divisions of the tube; so that the natural urate, which in powder originally occupied a given space, under the influence of a weak alkaline solution will fill up as a solid mass a space seventeen or eighteen times larger than its original room. If absolute alcohol—that is, a spirit devoid of water—is employed, no increase takes place, even after the lapse of a week or more; when, however, after the alcohol has been poured off, a solution of carbonate of lithium is subsequently added, the swelling of the urate goes on in the same way as when no spirit has been previously used. If small masses of the excretion are digested in a strong

solution of ammonia for a few hours, and afterwards dried and lightly powdered, it will be found that the property of puffing-up is entirely gone, and the same result ensues when caustic soda or potash is used instead of ammonia. I may here mention that I have examined the excretion of a large number of different reptiles and birds, and always with the same results whenever the specimens have been in a fairly fresh condition.

Having determined the physical condition of the excretion as it exists in animals whose urine is too deficient in water to hold the urates in solution, it appeared to me to be a matter of great importance to arrive at its chemical composition. The common idea is, as I have already said, that it consists of urate of ammonium; and, in the early analyses, ammonia was always found in it, but in small quantities only. There is no doubt as to the presence of ammonia in the urinary excretion of birds and reptiles, for we have only to add a caustic alkali, and the characteristic odor is at once developed; but it is important to go a step further, and to ascertain whether the uric acid, as it exists in the fresh excretion, is so combined as to form a true urate of ammonium. To effect this, I had many experiments made on the excretion of different birds and reptiles. From these the conclusion may be drawn that the uric acid in the pure substance is not combined with any fixed base, such as soda, potash, or lime, but that it is combined either with ammonia itself, or some organic base which readily yields ammonia.

The amount of ammonia varied very considerably in the different specimens which were examined; and, contrary to what I had anticipated, the specimens which were most perfect and exhibited least of all the appearance of disintegration were not those which yielded the most ammonia. It was also found that the swelling or puffing-up peculiarity was almost or entirely absent from those specimens in which the quantity of ammonia was greatest. This was well shown in the excretion of the royal python and of the Australian monitor (lizard), both of which specimens were much injured by decomposition. It would appear, therefore, that beyond a certain percentage, which seems to be equivalent to the formation of about 25 to 32 per cent. of urate of ammonium, the extra amount of ammonia results from some change which has taken place after the excretion has been passed. A close examination by the unassisted eye enables us to see that there has been some disintegration in the substance.

With the exception of those excreta in which decomposition has occurred, the amount of ammonia is far short of that which is necessary to the formation of the true diurate of ammonium. May it not be possible that the uric acid, when first formed, is in combination with some nitrogenized organic base, such as urea? If so, this would account for the results obtained. Or, again, may not an organic compound be first formed in the renal cells, which readily breaks up, yielding, among its chief products, uric acid and ammonia? This is a subject which I have not had leisure to investigate with sufficient thoroughness to be warranted in giving a decided opinion upon it. We have found therefore that the natural urate differs completely from the artificial in its physical properties, at least in so far as regards its power of becoming distended under the influence of water or carbonated alkaline solutions. It now becomes necessary to examine carefully its microscopic structure.

A paper of mine, published in the *Medico-Chirurgical Society's Transactions*, 1848 (vol. xxxi.), under the title of "Observations on certain Pathological Conditions of the Blood and Urine in Gout,

Rheumatism, and Bright's Disease," was illustrated by a plate, which contained, among other drawings, one which exhibited the microscopic appearance of the urinary excretion of the pigeon. This was the first time, I believe, that the minute characters of such excretions had been shown. The results of a reinvestigation of this subject, which I have recently made, will now occupy us for a few minutes, as it bears closely on the subject of renal calculi. I have examined the excretion of a large number of reptiles, birds, and invertebrate animals; and the drawings upon the screen, which are selected from a great many others, will give an idea of the appearances presented.

There is a great uniformity of appearance in the different specimens; in fact, it would be difficult or impossible to separate by microscopic characters the urine of a reptile from that of a bird; the only variation in the different drawings is that which appears in the size and prevalence of the larger spherules; for it will be noticed that there are many more of these in the large birds and reptiles than in the smaller birds, while the small spherules are of about the same size in all specimens depicted. No spherule in the excretion of the canary-bird approaches in size many which are to be seen in that of the rhea. The measurement of the largest spherules is 0.00072 inch, and the smallest about 0.00008 inch.

It seems to me that we should be ignoring all physiological principles if we did not assume that uric acid is originally excreted in the same way by all animals, be they reptiles, birds or mammals, including man—that if, as we have shown by fair evidence, it is formed in the cells of the kidney in one animal, it is so formed in another, although the different influences to which it may be subsequently subjected may cause an entire change from its original physical condition. In reptiles and birds we see that the uric acid, in combination with some base, is contained in the kidneys in the form of larger and smaller spherules, and we also see that these have a tendency to aggregate and form larger and larger balls or spherules, which are ultimately eliminated from the body. We see, in fact, that these animals are perpetually voiding renal calculi which, although small in size, are yet perfect in form and constitution. Their urinary tract is so constructed that no inconvenience ensues; but were such urine excreted by the mammal, it might at once lead to serious mischief.

May we not, however, get a lesson in pathology from reflecting on these facts? May not these spherules, which, as a rule, are soon dissolved in the watery urine of the mammal, occasionally escape solution, and become the nuclei of renal calculi? This idea is one which, up to the present time, I have never seen suggested, but it is at least worthy of some further thought.

I believe that I am correct when I say that hitherto it has been usual to regard both gravel and calculi as arising always from the precipitation of urinary principles which have been in the urine in a state of solution—a view which, as I have already shown, has some truth in it, though I think that, before I shall have finished the present lecture, I shall be able to lay before you facts which may cause some modification in the opinions which have been commonly held.

In examining several different calculi which had been passed soon after their descent into the bladder, I have found that some are apparently simple—that is, when cut they exhibit a uniform structure throughout; such calculi, however, are generally very small, the largest not exceeding in size a pin's head. Others are evidently compound in their structure, containing a central nucleus sur-

rounded by layers which may be more or less numerous in different calculi; in fact they resemble, when seen through a glass, the larger form of the vesical calculus.

Let us now study more closely these two forms of renal calculus, and let us begin with the more simple kind. I will select one which is very minute indeed—a mere point of matter. This, when placed in a small cell under the microscope, presented an appearance which is exhibited in the enlarged drawing on the screen. It is seen to be irregular on its surface, as if composed of a number of little beads or grains aggregated together. Let us now watch the result of putting into the cell a few drops of a solution of carbonate of lithium. After a few minutes the superficial beads become more or less transparent, and exhibit in many instances the appearance of small cells which have been denuded of their contents. The little calculus soon has a translucent ring around it, which becomes broader and broader as the action of the carbonate of lithium spreads, the opacity of the calculus remaining in the centre only. Under the continued action of the lithia salt this last remnant of opacity also disappears, and the whole calculus is reduced to a translucent substance, which has the appearance of being made up of a great number of little vesicles. If polarized light be employed, this is seen to contain matter having a crystalline structure, but the still further continued action of the alkaline fluid ultimately removes this too, and the calculus is then seen as a mass apparently made up of colloid matter in a more or less membranous shape.

Before proceeding to the examination of the more complex renal calculi, I wish again to draw your attention to the spherules from the excretion of the serpent and the bird, that you may see how they behave under like circumstances. Of course the largest of these is very much smaller than the minutest calculus that we can make use of, but this fact in no way interferes with the observation of such spherules.

Let us first imagine that we put a particle of the white excretion on a microscopic slide in a drop of alcohol, which does not alter the spherules, and, after covering it with a thin glass disc, examine it carefully. Some spherules are seen to be large, some smaller, and some smaller still, till at length a size is reached which seems to be the smallest which they are capable of assuming. Next, let us place a moistened finger upon the thin upper glass and rub it upon the powder for a few seconds, using a fair pressure; then, on re-examination under the microscope, the whole of the spherules have disappeared, and in their place are seen innumerable irregularly rounded particles of a pretty uniform size. If, instead of using pressure, we allow the alcohol on the slide to evaporate and introduce a drop of a solution of carbonate of lithium, and then watch what follows, we shall see that the outlying spherules in the field are usually the first to be acted upon, and exhibit the following appearances:—After a few minutes only some of the spherules show a transparent line around them, which, on close examination, is seen to be composed of transparent beads; this ring grows larger and larger, so that in a short time no opacity remains, save in the centre of the spherule. As time goes on, with renewed application of the alkaline solution the dark central mass gets smaller and smaller, and at last altogether disappears, our original spherule being changed into a round membranous mass, without definite structure, containing crystalline matter which powerfully polarizes light, which matter also in turn gives way under long-continued action of the lithia solution.

If we compare this description of what I may call the "dissolving view" presented to us by the changes in the normal spherule of the bird or reptile, with that before given of those which occur in the small or rudimentary calculus, we cannot help being struck by their close resemblance; in fact, whatever differences there may be, seem to be little more than differences of degree. Surely this must make us reflect on the possibility of there being a close relationship between the two, and may fairly suggest to us the question whether the rudimentary uric calculi found in man may not be merely aggregations of spherules—the product of the original cell-formation of the uric acid. In the case of the bird and the reptile we are sure that the spherule cannot have been deposited from uric acid previously dissolved in the urine, seeing that there is no such fluid to dissolve it; and it may be that in the case of man also the individual components of these calculi are simply the original cell-formations of uric acid which have become somewhat altered in chemical composition, and rendered less soluble. If this be true, and if we can show that these rudimentary calculi are not produced by the precipitation of uric acid from the urine, we must at once remove them from that class of deposits which are called sand or gravel, seeing that these latter, whatever their size, have a totally different structure. It is to the spherular grains and the more complex structures that I shall confine the name of renal calculi.

In several renal calculi which I have examined I have found some spherular bodies—masses of irregular shape, resembling much the partially broken-up pyramids, into which the spherules of the excretion from reptiles and birds frequently split when carefully rubbed and only partially disintegrated. I have also found crystals of oxalate of calcium, many of them octahedral in shape. From these examinations I have formed the opinion that the appearances in the nucleus may arise from a slow alteration taking place in the first-formed or spherular urates by the action of the fluid urine upon them, causing the gradual decomposition of the original ammonia salt, and an increase of its insolubility, leading also to the subsequent production of oxalate of calcium, which we know is often the result of the action of a ferment on uric acid.

If, instead of a very small and rudimentary calculus consisting merely of an aggregation of grains, we take one of a larger size and more complex structure—one, for example, one-eighth or one-sixth of an inch in diameter—we find that around this granular central nucleus layers are arranged in concentric order—that is, the calculus becomes laminated, the number of layers depending greatly on the length of time during which it has been exposed to the action of the urine. These layers vary much in thickness and also in color, and probably are most of them originally composed of some urate, rather than uric acid itself. The subsequent action of an acid urine on a deposited layer of a urate would often slowly reduce the urate into a state of free uric acid. In examining renal calculi which have this laminate arrangement, I have frequently found the central nucleus almost devoid of color. What is the cause of this peculiarity of the nucleus? The only explanation which at all satisfies my mind is that the nucleus granules have never been in a state of solution since they were formed in the kidney cells, and therefore have never become recrystallized with the coloring matter of the urine—in fact, that they are in a condition very much like that of the renal spherules of the lower animals. The color of the layers—a pale pink or dark fawn—is not at all difficult to explain, for whenever uric acid or urates

are deposited from solution, they invariably take with them the coloring matter of such solution, which becomes intimately united with the crystalloid, giving it an altered shape.

Influence of Diet.—There can be little doubt that the occurrence of gravel and calculus is largely influenced by the diet, but on this subject I feel sure that the opinions frequently held are not altogether correct and require to be reconsidered. As we shall find that a gouty diathesis is so potent in the production of the diseases under review, it will be quite safe, in so far as the discussion of food is concerned, to assume that what tends to produce gout tends also to develop calculus, and that the diet which is of avail in the treatment of the one disease is equally so in the management of the other. It will be desirable to turn our attention to the principal groups of aliments and ascertain what influence they have upon the formation of uric acid and also upon its condition with respect to solubility.

1. *Sugar.*—The most common of the non-nitrogenized principles contained in food is starch, seeing that it forms 70 per cent. of wheaten flour, and almost the whole of many of the simple amylaceous articles of food, as rice, maize, arrowroot, sago, etc.; also of the potato, turnip, carrot, and so on, when these latter are dried. It can be shown that, when taken into the alimentary canal, starch is soon changed into glucose sugar by the action of the saliva and pancreatic juices; and, when cane sugar is taken, the same change ensues, so that however carefully sugar is avoided as an article of food, it is still abundantly formed in the canal when amylaceous matters are eaten, and the result is the same whether a pound of starch in any of its dietetic forms or a pound of cane sugar be taken.

There is a very popular idea that sugar causes what is termed acidity, and hence it is scrupulously avoided by many. Is this true? Between two or three years ago I was much struck at seeing an American surgeon of great repute putting lump after lump of white sugar into his tea, and I asked him why he did so. He told me that in the States it is a common habit to take sugar thus as a preventive of heartburn, and that he took it for that purpose. His answer made a strong impression on my mind, and since then I have often questioned dyspeptic patients as to their experience on this point. At first nearly all exclaim, "Of course sugar causes acidity," but as yet I have failed to find anyone who could assure me, from personal experience, that the eating of lumps of ordinary white sugar produces more so-called acidity than taking any other article of diet. It must be borne in mind that I do not for a moment include sweetened fruits, and such-like substances, in the same category as simple sugar. One can hardly believe that the eating of a lump of cane sugar would seriously add to the glucose which is daily produced in the alimentary canal of an individual living on an ordinary mixed diet. Let us see what has been found experimentally with regard to the influence of sugar on the production of uric acid. Böcker says that the effect, in man, is to lessen the quantity of that principle, and Bischoff and Voit have proved that, in dogs, starch produces the same effect on the urinary excretion as sugar, so I think we may say that there is no increase in the uric acid when sugar is taken.

I must devote a few minutes to the discussion of a most important subject—viz., the influence of different alcoholic beverages on the production of uric gravel and renal calculi. We must remember that all such beverages contain alcohol united with different proportions of water, some little more than this; others, however, contain sugar together with coloring and so-called extractive matters, also

salts of potash and lime united with vegetable or mineral acids. Many wines also contain a certain amount of some free organic acid. Now, have we any facts with regard to the special effects of different wines in the diseases which we are now considering? I think we have many, and much information which we can use to guide us in the prevention of such diseases. It may, as I believe, be confidently asserted with respect to gout, that, with an absence of alcohol in any shape, coupled with an absence of hereditary predisposition derived from alcohol-drinking ancestors, the disease would be practically unknown.

It is most essential to separate the different kinds of alcoholic beverages from each other in estimating their tendency to produce disease. Thus, alcohol in the form of distilled spirits, although when taken in excess it causes serious mischief, injuring the liver, kidneys, heart and other organs, still has little or no power of producing the uric acid diathesis, or, at any rate, the gouty development of it. In spirit-drinking countries, or among spirit-drinking families, gout is unknown. Look at Scotland and its whisky-drinking classes—the disease is practically absent, hardly ever seen in the hospitals. Look at Poland, where they drink a kind of arrack; the same holds good.

When, however, we investigate the influence of wines we shall find a different result. Drinkers of the common light wines, such as the red Bordeaux and the Rhine wines, suffer but little, while, among the same nations, those who indulge freely in beer are by no means free. The natural light wines, in which the alcohol is small in amount, while there is an almost complete absence of unfermented matter, which contain, also, a considerable quantity of acid vegetable salts, are little liable either to produce gout or to lead to the formation of calculus or gravel. On the other hand, the Peninsula wines and those which resemble them, which are stronger in alcohol, contain much unfermented matter, and are almost devoid of the vegetable salts, have great gout-producing power, and lead readily to a condition of urine favorable to the production of gravel and calculus.

We come, lastly, to the malt liquors, ale, beer, stout, and porter. From my own experience, and I believe it is also the experience of all who have attended to the subject, I can confidently assert that these beverages have a great tendency to produce the uric acid diathesis. Compare the hospitals of Edinburgh and Glasgow with those of London; in the former gout is scarcely known, in the latter the disease is common, the difference, as I believe, being chiefly due to the different beverages drunk by the working classes of the two countries; it is, in fact, the difference between whisky and malt liquors.

It is necessary that we should at least endeavor to ascertain what principle or principles, present in some of these alcoholic beverages, absent from others, lead to the development of this diathesis or aggravate it when it is already manifested owing to hereditary or other causes. It cannot be the alcohol alone; this, I believe, can be fully and satisfactorily proved, seeing that large groups of people whose custom is to drink freely of distilled spirits are yet free; instances are to hand in Scotland, Sweden and Norway, and Poland. It cannot be the sugar alone; for, although the partially fermented wines and malt liquors contain sugar, yet sugar added to distilled spirit does not appear to produce the uric acid diathesis. It cannot be the acidity alone; for the wines which are most harmless are quite as acid or even more so than malt liquors and the Peninsular wines, and many people who strongly object to the least acidity in wines, will often take lemon

juice to an extravagant extent. If, then, neither the alcohol, nor the sugar, nor the acidity by itself is the cause of certain beverages proving so injurious, is it a combination of any of these that does the harm? We already know that the combinations of alcohol with sugar, and that of alcohol with acid salts, are innocuous as far as the uric acid diathesis is concerned. What, then, is there left for us to fall back upon in explanation of the peculiar properties which some of these beverages possess, while others are devoid of them? The only conclusion that I can arrive at with my present knowledge—and it is the result of much thought during many years—is that it is something which is a result of imperfect fermentation, and you will find that it is those beverages in which fermentation has commenced, and has been allowed to proceed to a certain extent and has then been checked, which, of a certainty, cause gout, and probably lead also to the production of gravel and calculus. If I am asked to state more exactly what this principle is, I cannot do so; it may be an influence only, a condition of matter—a ferment.

In connection with this subject, however, I must return for a moment to that of sugar, which, I told you, had, as I thought, been regarded askance without due cause. I would say that I do not for a moment classify with sugar either sweetened fruits or vegetables; for I am quite sure that such articles of diet will frequently produce heartburn and other dyspeptic annoyances in individuals who are not in the least inconvenienced by sugar itself. I cannot help thinking that these contain a something which is not simple sugar, but a substance which is the result of the long contact of the sugar with the fruit or vegetable juices, a kind of semi-fermented matter—in fact, that same “something” which exists in the stronger wines and the various malt liquors. Of this I feel confident, that in many cases where sugar, whether by itself or in tea, coffee, and light puddings, does not disagree, and where fresh fruit, although sweet, produces no discomfort, the combination of sugar with these juices, if time has been given for them to act upon each other, will often cause well-marked dyspeptic symptoms. But, it may be said, if so, a ripe orange cannot be a good thing to eat, as it contains both sugar and acid juice, and these substances have been in contact with each other for a long time. I answer, not necessarily so; so long as the orange exists as a fruit, with its botanical structure intact, so long there may be no change taking place between its different constituents. We have a striking analogy to this in the case of the bitter almond. When whole this seed contains the crystalline amygdaline and an albuminous ferment. Separate one of these from the other, and each by itself is innocuous; crush and moisten the almond, prussic acid is immediately formed, and the union of the two principles is the production of a deadly poison.

—The death is announced of Dr. George Miller Beard, of New York, from pleuro-pneumonia. Dr. Beard was a voluminous writer. His name will be familiar to professional readers in connection with subjects which are not generally regarded as worthy the time and attention of busy practitioners. His death, though sudden, was not altogether unexpected by himself, and he is said to have philosophized, as his end approached, on the rapidly progressive changes he was undergoing, and to have expressed a wish to be able to record the thoughts of a dying man.

Original Papers.

REMARKS ON THE REMOVAL OF THE ENTIRE TONGUE WITH SCISSORS BY THE WHITEHEAD METHOD.

By W. H. A. JACOBSON, M.B., F.R.C.S. Eng.,

Assistant-Surgeon to Guy's Hospital, Examiner in Surgery at the University of Oxford, Surgeon to the Royal Hospital for Children and Women.

HAVING made use of the above method in two cases, I wish to state my experience of it, as the safety and extreme simplicity of Mr. Whitehead's operation do not appear to be as yet sufficiently recognized.

The ages of my patients were forty-nine and fifty-seven. In both “soreness” of the tongue had existed for a very long period. Thus in the first case a small sore had been produced twenty-eight years before the operation by a pipe being broken in the patient's mouth. Since this time the tongue had always been sore off and on, especially after smoking too much, or after indulging in wine. A long, valley-shaped, ulcerated fissure occupied the middle and posterior thirds of the tongue on the left side; with this coexisted numerous smooth bald patches and others of a “leucomatous” nature. The ulcer extended so far back, and was so intensely painful, that before an anæsthetic was given it was impossible to define its posterior limit. Thus it would have been a matter of great difficulty to get the loop of an *écraseur* behind it; and even when this was done, the loop, when tightened, would certainly have come dangerously near the ulcer. In this the superiority of Mr. Whitehead's method was strikingly shown, as it enables the surgeon to place his line of section of the tongue clearly and decisively behind the disease. In the second case the disease had also lasted a long time. A sore had first appeared on the right side of the tongue twenty years before admission; this used to heal and then break out again at intervals of varying length. For sixteen months the ulcer had been permanent and increasing steadily. On admission it was about an inch and a half in length, involving chiefly the middle third of the tongue, intensely painful, and bleeding freely when touched. The upper surface of the tongue showed manifold evidence of past irritation. In both cases glandular enlargement coexisted. In the first case this was marked upon the left side, in the second there was some enlargement in both submaxillary triangles, though to a less degree. Thus, owing to the long duration of the disease, the glandular infection, and the syphilitic taint, neither of the cases was a favorable one for operation.

The first patient was operated upon Dec. 1st, 1881, and left the hospital Jan. 4th, 1882, expressing great relief from the removal of his chief source of pain. The glands in the neck, which, as already stated, were enlarged before the operation, did not admit of interference, and the patient died from the effects of their ulceration in the following March.

In the second case the operation was performed April 25th, 1882. The patient left the hospital on May 30th.¹ The glands in this case also enlarged, subsequently suppurated freely, and then subsided. My old friend, Dr. Eastes, of Folkestone, who sent the case to me, tells me that the patient

¹ The operation wound healed in seventeen days, both patients were kept in for some time later in order to watch the enlargement of the glands.

was able to follow his employment till the middle of December, 1882, and that at the present time (Jan., 1883) his life is drawing to a close, owing to the enlargement of the glands and their pressure on the trachea and oesophagus. Dr. Eastes adds: "He has very little pain compared with that of the tongue before the operation." In both cases the operation passed off without any hitch save for the dyspnoea from the anæsthetic which was present in both cases, especially in the second. The hæmorrhage was well within control by the precautions mentioned below. The amount of sloughing in the floor of the mouth was very slight; for the first two days the wound was covered with a layer of dry glazed blood-clot, after this granulations sprang up rapidly. In the first case immediately after the completion of the operation I brushed over the floor of the mouth with a solution of the chloride of zinc (twenty grains to one ounce), to minimize the future fetor and sloughing. This precaution was superfluous, considering how very slight the after-sloughing was. I believe that it was also pernicious, and caused a certain amount of cellulitis, which delayed the patient's recovery and increased the glandular enlargement which existed prior to the operation. It should be stated that in this patient there was a cicatrix of an old abscess in the neck, and that perhaps the existence of "residual" inflammatory products made the patient very liable to cellulitis. The most efficient and painless way of keeping the mouth clean in such cases is the frequent use of iced Condy's fluid by means of a modification of Dr. Thudichum's syphon douche. The patient will readily take to using this himself.

I propose first to quote the chief details of Mr. Whitehead's method,* adding a few remarks which have been suggested by my experience of it, and then to contrast it with other methods, as Mr. Whitehead's operation must stand or fall according as his belief that it is simpler and safer than any other is verified or not by the experience of other surgeons.

1. "The mouth is opened to the full extent with a Mason's or any other suitable gag, the duty of attending to this important part of the operation being entrusted to one of the two assistants required."

The position of the patient during this operation is of great importance. As a rule it will be best to turn the head well to one side; by this means the blood will collect readily in the pouch of the cheek on this side, and one assistant, who with a finger draws out the angle of the mouth, is to frequently sponge out the blood as fast as it collects within the cheek. The sponges should be small, perfectly clean, wrung each time out of iced Condy's fluid, firmly secured to the sponge-holders, and promptly supplied. Another assistant, who has charge of the gag, should from time to time with similar, but rather larger sponges, wipe out the fauces, so as to prevent any collection of blood there. In whatever way the tongue is removed the operation is usually, especially at first, complicated by dyspnoea. A little patience, and removal of the gag, if necessary, until the patient is more fully "under," will usually be sufficient. Chloroform is usually indicated in patients who have reached the time of life at which epithelioma of the tongue is generally operated upon. Ether, by the increased secretion of mucus which it causes, adds to the dyspnoea which from one cause or another is usually present in these operations; this anæsthetic is, of course, especially to be deprecated if the surgeon should be led to

make only a partial use of the scissors, and divide the root of the tongue with the thermocautery. If the position of the patient's head, turned well to one side, is not found satisfactory, the patient should be propped up, and the chin depressed forwards, so as to keep the blood away from the fauces. This position will, however, be found less convenient to the operator, it is less safe for a patient under the influence of an anæsthetic during a severe operation, and it does not give equal facilities for the safe collection and ready sponging away of blood, as that which has been mentioned above.

One or two other matters require to be alluded to, though to some they may appear obvious and trivial. While I entirely believe that this method of Mr. Whitehead's is by far the simplest of all and perfectly safe, there is no doubt that it calls for special coolness and decision on the part of the operator, and promptness with their help from the assistants and nurses. A good light is most essential, and no crowding of spectators should be permitted. In making arrangements for a good light the surgeon should remember that while the operation itself takes but a short time, the getting the patient under the anæsthetic may be much prolonged.

2. "The tongue is drawn out of the mouth by a double ligature, passed through its substance an inch from the tip. This ligature is given in charge of the second assistant, with instructions to maintain throughout the operation a steady traction outwards and upwards."

By pulling on the tongue in this way the surgeon will remember that the upper orifice of the larynx is rendered more patent. This, of course, facilitates the entrance of blood, and should make the assistants more watchful to sponge out the cheek and also the fauces more efficiently. On the two occasions on which I have made use of this method I found it preferable to hold the ligature myself, as this not only gave a better view of the cavity of the mouth, but also made it more easy to keep up the firm traction which of itself serves to arrest the hæmorrhage from the smaller vessels in the substance of the tongue.

3. "The operator commences by dividing all the attachments of the tongue to the jaw and to the pillars of the fauces, after the manner suggested by Sir J. Paget, with an ordinary pair of straight scissors."

4. "The muscles attached to the base of the jaw are then cut across with a series of successive short snips of the scissors, until the entire tongue is separated on the plane of the inferior border of the lower jaw, and as far back as the safety of the epiglottis will permit."

5. "The lingual or any other arteries requiring torsion are twisted as divided. It is generally found that a moment's pressure with a small piece of sponge, held in sponge forceps, suffices temporarily, if not permanently, to arrest any bleeding; it is, however, regarded as desirable to twist, either immediately or after the tongue is removed, every bleeding vessel."

The surgeon must here follow Mr. Whitehead's directions to the letter. If a pair of scissors curved on the flat be made use of, the operator will find himself getting to an unequal depth into the floor of the mouth, and thus exposing himself to the risk of additional hæmorrhage, and of cellulitis from needless interference with the cellular tissue and planes of fascia, which are here met with. The scissors should be perfectly straight, and cut sharply up to the very points, which should be blunt, otherwise they will hitch in a very embarrassing way in the soft parts which are being divided.

* They will be found in a pamphlet on *Excision of the Tongue* (Churchill, 1881).

Both my cases bore out in every particular the correctness of Mr. Whitehead's statement as to the amount of hæmorrhage and the facility with which it may be met. The oozing is of course free, but it may be kept under control by keeping the patient's head in the position already mentioned, and by maintaining steady traction on the tongue, which, as is well known, comes forward quickly as soon as the mucous membrane of the floor of the mouth and the palato-glossi are divided, each successive snip bringing the tongue more and more under the surgeon's control. In both my cases only the ranine and lingual arteries on the left side required torsion, the hæmorrhage from the fellow vessels on the right side being readily arrested by firm sponge pressure. In one case there was some difficulty in twisting the left lingual, owing to the softness of the tissues, and, this being so, this vessel and the surrounding tissues were transfixed with a tenaculum, and a silk ligature applied and cut short.³ In neither case was there the slightest after-hæmorrhage, intermediate or secondary, though, as already stated, both patients were unfavorable subjects for operation, from the long duration of the disease, the gland infiltration, and the well-marked taint of syphilis.

The tenaculum is an instrument with which the surgeon should be provided in this operation as well as with torsion-forceps and scissors. It is most useful not only for the meeting of hæmorrhage, but also for the picking up of suspicious patches in the floor of the mouth; for the removal of these with scissors the tenaculum holds as well as any kind of forceps, and has the further advantages of being small, handy, and little in the way. In cases where after removal of the tongue hæmorrhage is dreaded a tenaculum should always be at hand by the bedside.

6. "A single loop of silk is passed by a long needle through the remains of the glosso-epiglottidean fold of mucous membrane, as a means of drawing forwards the floor of the mouth, should secondary hæmorrhage take place. This ligature may safely be removed the day after the operation; and, as it is invariably a source of annoyance to the patient, it is always desirable to adopt this rule."

I did not adopt this precaution in either case, and in neither was there the slightest after-hæmorrhage. It not only must cause, as Mr. Whitehead allows, great discomfort to the patient, but the silk will rapidly become foul, and by its mere presence will tend to irritate parts which are now extremely sensitive.

A few remarks will now be made upon the other methods of removing the entire tongue, by way of contrasting them with Mr. Whitehead's plan.

(a) *Removal by the galvanic écraseur.*—The use of the heated loop of wire has not of late years kept up its early reputation, and chiefly for the following reasons: 1. The necessary apparatus is expensive and often cumbersome. 2. It causes a most extensive slough, which not only takes some time to separate, thus exposing the patient to the risks of septic broncho-pneumonia and septicæmia, but also, when separating, may give rise to hæmorrhage. This hæmorrhage may be very difficult to arrest owing to the sloughy state of the tongue, and is especially dangerous at this time in consequence of the weakly state of the patient, whose recovery from a very severe operation is not likely to have been hastened by the sloughy condition of his mouth. Other objections which the galvanic écraseur shares with the ordinary instrument are:

3. That owing to the great strain which is put upon it, the wire must, however carefully fixing needles have been introduced (and this is not always, when the ulceration extends far back, an easy matter), draw dangerously, as it is gradually tightened up, upon the site of the disease. 4. The risk of breaking. The thermo-cautery has been used in some cases. It is, however, an inconvenient instrument to make use of far back in the mouth, and it has the further disadvantage, which is also shared by the galvanic écraseur, that as it sears through the tissues of the tongue it so alters the look and feel of parts that the surgeon may leave diseased portions behind without knowing it. Theoretically, of course, this may be avoided by cutting very free of the disease, but in practice this is not always easy. If, to facilitate the tongue's coming forward, the mucous membrane at the side and the pillars of the fauces are first snipped through with scissors, and the tongue then severed with the thermo-cautery, the patient has still to run all the risks of the detachment of a large slough in his mouth.

(b) 1. The ordinary écraseur, though it causes distinctly less sloughing than the galvanic loop, still leaves the parts in a much more bruised condition than a pair of clean cutting scissors. 2. There is the serious danger of the loop during the extreme tightening which it undergoes drawing close to the cancerous spot. 3. There is the risk of the wire breaking, though this risk may be much diminished by splitting the tongue and dividing each half separately, as recommended by Mr. Morratt Baker. Another objection to the wire écraseur is often seen at the close of the operation, when the loop, though screwed up to the uttermost, is still too coarse to divide the lingual artery, which is pulled out by the écraseur, and often requires division with scissors, and then torsion or a ligature. 4. I have already alluded to the dyspnoea which is always liable to accompany operations for the removal of the tongue; the swollen condition of the organ produced by the pressure of the écraseur sometimes produces this complication to a serious degree.

(c) Mr. Syme's operation of dividing the symphysis has been recommended when the floor of the mouth is involved. It is not only an extremely severe measure, but it is objectionable because in these patients, who are often much reduced in strength, it is liable to be followed by necrosis and tardy union of the sawn surfaces, which will interfere seriously with the patient's comfort and ability to take solid food. Furthermore, it appears to me to be needless, as diseased tissues in the floor of the mouth can usually be removed by scissors and a tenaculum, aided, in severer cases, by an incision in the submaxillary region for the extirpation of glands.

(d) The incision through the cheek has the advantage of giving additional room, and offers facilities for adjusting and watching the action of the écraseur. It heals readily, but the scar may be objectionable, and in any case the wound left after removal of the tongue is, at first, so painful that no additional wound should be made, if it can be

removed of the tongue by the écraseur, patients succumb to rapidly fatal affections of the lung, which come on either as a part of a general pyæmia or as a more local disease from the direct passage downwards of fetid emanations from the sloughing wound. To obviate these risks Mr. Barker admits pure warmed air to the lungs by means of a preliminary tracheotomy, the mouth and nostrils being plugged with cotton-wool, and the floor of the mouth being drained by means of a long tube passed through under the chin into a basin of Condy's fluid. I believe that these ingenious precautions, which must be somewhat irksome to the patient, and one of which, the tracheotomy, involves some additional risk, will be rendered superfluous by Mr. Whitehead's method, owing to the clean-cut surface and little liability to sloughing which this operation leaves.

³ Everyone who has demonstrated anatomy knows how commonly the lingual arteries are unequal in size.

⁴ Mr. Barker has shown how very commonly, after extensive

avoided. The readiness with which the tongue comes forward when removed by Mr. Whitehead's method has already been alluded to.

(e) Professor Billroth has practiced ligature of the lingual arteries preliminary to removing the tongue with scissors.³ Dr. Elder, of Nottingham, in recording a successful case of removal of the tongue by Mr. Whitehead's method, states that in repeating the operation he shall ligature the linguals first, as he considers the danger from hæmorrhage greater than Mr. Whitehead is inclined to admit. Mr. Treves,³ in the account of a case in which he removed the tongue by scissors, though, as he frankly admits, not by Mr. Whitehead's method, correctly speaking, as this was departed from in several important particulars, found the hæmorrhage so profuse that he states that in future he should first ligature the linguals.

It may be worth while to point out here that this step is by no means always easy of execution. As in a case recorded by Dr. Warrington Haward,⁴ it may be impossible to find the artery above the hyoid bone, owing to enlargement of the lymphatic glands and general infiltration of the tissues. If it be sought for close to its origin from the external carotid, the superior thyroid or facial may be mistaken for it, this being more likely if the point of origin of these vessels is at all abnormal, or if two of them arise together. Another difficulty which occurred to one of the most experienced operators in Europe, Professor Billroth, may be told in his own words:—"A. K—, aged fifty-seven, had first noticed pain and hardness of the right half of the tongue six weeks before admission. A cancerous ulcer, which extended far back, was seen on the right side of the tongue; no enlarged glands could be felt; he could only open the mouth to a slight extent. In order to avoid hæmorrhage as much as possible, I commenced by ligaturing the right lingual artery. I performed the operation *lege artis*, but had most extraordinary difficulties in discovering the artery. Finally, I thought I saw it pulsating, and placed a ligature round it. In removing the lower and under portions of the tongue, tolerably free hæmorrhage occurred from the lingual artery, and I had my doubts as to whether this vessel had actually been tied. The patient died two days later of septicæmia. Post mortem we discovered that the lingual vein had been ligatured instead of the artery. Every surgeon knows the difficulty of tying the lingual artery in old people; the vessel lies so deep, that it is very difficult to distinguish it from thick-walled, distended veins, especially when, owing to heart disease, as in this case, the veins pulsate. Never previously had I met with a lingual vein of such thickness."

I believe that any surgeon who, having made use of other methods of removing the tongue, shall be led to try Mr. Whitehead's operation, will give this a decided preference, as being equally safe, while it is far simpler and more speedy than any other.

— THE American journals announce the death of Dr. Walter Burnham, a surgeon of distinction in the States. Amongst other services he conferred upon the profession, was the part he took in the passing of an Anatomy Act for Massachusetts.

³ In his *Clinical Surgery*, translated by Mr. Dent for the New Sydenham Society, Professor Billroth speaks of having ligatured the lingual artery twenty-seven times.

⁴ To compare with the above two cases, Dr. Marshall, of Preston, records a case in which this operation was completed in four minutes and a half, the total loss of blood being estimated at rather less than an ounce.

⁴ Clin. Soc. Trans., vol. x., p. 130.

FOUR CASES OF EXCISION OF THE ENTIRE TONGUE BY SCISSORS.

By FREDERICK TREVES, F.R.C.S.,

Assistant Surgeon to, and Senior Demonstrator of Anatomy at, the London Hospital.

In the four following cases the entire tongue was removed from the mouth by scissors, by what is known as Billroth's method, the lingual arteries having been previously ligatured in the neck. For one of the cases (Case 2) I am indebted to the kindness of my colleague, Mr. James Adams, by whom the operation was in that instance performed. The procedure adopted in each of these cases was precisely the same, and was briefly as follows: The patient having been anesthetized, the linguals were first secured in the neck. Each vessel was reached by a curved incision that commenced behind at a point some little way below the jaw, opposite the anterior edge of the masseter, and that was continued down to the level of the hyoid bone, and finally carried up to a point behind and below the symphysis menti. The submaxillary gland having been displaced, the artery was exposed by cutting through the hyoglossus muscle in the floor of a triangle formed above by the ninth nerve, and below by the converging bellies of the digastric muscle. In no instance was there any difficulty in securing the vessel, although, owing to the depth of the incision, the proceeding is somewhat tedious. Care should be taken not to disturb the submaxillary gland more than possible, and it is most desirable that no part of the gland should be included in a ligature. Billroth, in speaking of ligaturing portions of the pancreas in pyloric resection, has drawn attention to the evils that often follow upon the application of a ligature to a solitary gland; and Case 4 serves to illustrate some of these inconveniences. Both arteries having been secured, the mouth is forced open by a Mason's gag, and the tongue drawn forwards by means of a stout ligature passed through its anterior part. The entire organ is then cut out with a pair of strong straight scissors. The frænum is first freely divided, and one blade of the scissors being thrust beneath the mucous membrane of the floor of the mouth, that structure is divided on each side between the tongue and the jaw, as far back as the epiglottis. Returning again to the middle line, the hyoid muscles are divided from before backwards, and, after a few vigorous snips with the scissors, the organ is free. The bleeding that follows is very insignificant, and usually is immediately arrested by firm pressure with a sponge. It is only far back, in the region of the tonsil, that any bleeding may occur that does not cease almost spontaneously. In two of the cases given below a touch with the cautery at once checked the oozing; in the other instances it required no treatment. The cut surface left after the removal of the tongue can be readily inspected by bending the patient's head a little forwards, and pushing up the floor of the mouth from the outside. As illustrated by these four cases, the operation may be spoken of as practically bloodless. For the first three days after the operation the patient is fed entirely through an india-rubber catheter passed into the gullet from the nose. On the fourth day he is able to feed himself, and usually finds it most convenient in swallowing his food to place the head very much to one side, so that the fluid may run by the side of the larynx into the œsophagus. The patient is up on the seventh day, if all goes well, and strong enough to leave the hospital by the tenth or eleventh day after the operation. In the cases detailed below

the mouth was kept constantly washed out with iced permanganate of potash water for the first week after the incision. When cough is complained of, considerable relief is given by causing the patient to inhale steam charged with a little compound tincture of benzoin. The incisions in the neck were dressed with carbolized lint, and all healed, with the exception of the right incision in Case 4, by first intention. Three patients out of the four made a rapid recovery, and were up and about by the seventh day. The fourth patient, a feeble and badly nourished man, died on the fifth day of pneumonia.

I think that the following advantages may be claimed for this procedure of Billroth's:—1. It is comparatively simple and requires no elaborate apparatus. 2. By its means more of the tongue can probably be excised than can be removed by the *écraseur*, no matter how applied. With the *écraseur* it is somewhat difficult to vary the exact amount to be removed in particular cases, since the surgeon can only deal with what can be included in a noose. It may be noted, moreover, that with the scissors an extensive excision can be performed without such complication as division of the jaw or cheek, or an opening into the floor of the mouth above the hyoid bone. 3. The procedure is practically bloodless, and the great source of danger in tongue operations is thus removed. It appears to me that on this ground Billroth's method is infinitely superior to Mr. Whitehead's modification of the same. Mr. Whitehead, it is well known, removes the tongue with scissors, but without previous ligation of the lingual arteries. The operation has been successful in the skilful hands of the surgeon who introduced it; but it would seem to subject the patient to a totally unnecessary and serious risk, a risk that is not counter-balanced by any other obvious advantage. 4. The wound left after the removal of the tongue is, in a surgical sense, extremely simple, and is actually a clean incised wound. Such a wound must compare favorably with the external charred surface left after the galvanic *écraseur* and with the lacerated wound that follows the use of the cold wire. When the tongue is removed by scissors there are no superficial sloughs to come away from the floor of the mouth, and there is therefore less opportunity for the formation of a fetid discharge. 5. The intra-oral part of the operation occupies but a brief space of time, the actual excision requiring probably about two minutes. It is needless to say that when a patient is anesthetized a prolonged operation upon the tongue is objectionable in many ways. The cold wire, if cautiously applied for the removal of the entire tongue, will usually not have cut its way through in thirty minutes.

6. Through the incisions made in the neck the surgeon is enabled to readily remove enlarged glands and to detect such bodies when they are not to be felt through the skin.

CASE 1.—Male, aged fifty-six. Epithelioma extending over the greater part of the dorsum of the tongue; the floor of the mouth was free; there were no enlarged glands to be felt. The ulceration had commenced four months previously. On June 7th, 1882, I removed the tongue by the method above described. No hæmorrhage except a little from the posterior part of the incision, which was readily checked by a touch with the actual cautery. The patient was in very feeble health at the time of the operation. He did well for six days, when he developed a sharp attack of pneumonia, of which he rapidly died. The wounds in the neck were almost entirely healed. The autopsy showed no evidence of pyæmia.

CASE 2.—Male, aged fifty-three. Admitted under

the care of Mr. Adams, July 20th, 1882. The epitheliomatous ulcer involved the centre of the tongue, extending to the edge. It had commenced two months previously. Two small glands could be detected below the jaw. On Aug. 3rd the tongue was removed. No hæmorrhage to speak of. The incisions in the neck healed by first intention. The patient was up and about the ward on the seventh day, and left the hospital to return to work on tenth day after the operation. His temperature after the operation never rose above 99°.

CASE 3.—Male, aged forty-five. Extensive epithelioma of the left side of the tongue of four months' duration. The floor of the mouth was free. On October 6th, 1882, the tongue was removed. No hæmorrhage to speak of. Highest temperature reached after the operation was 101° on the evening of the third day. The temperature was normal on the fifth day. The wounds in the neck healed by first intention. The patient was up and about on the seventh day, and left the hospital on the eleventh day after the operation. I have lately (January, 1883) seen this patient. The surface of the stump is well healed and the patient is perfectly comfortable and in good health.

CASE 4.—Male, aged fifty-eight. Extensive epithelioma of the right half of the tongue. The posterior limits of the mass could not be well made out. Induration was extending towards the floor of the mouth. Speech was much affected and great pain complained of. There were some enlarged glands in the neck on the right side. On November 1st, 1882, the tongue was removed. The enlarged glands were removed through the incision made for ligaturing the right lingual. In removing these glands the salivary gland was damaged, and I thoughtlessly included a little piece of it in a catgut ligature. The cancer proved to have extended very deeply, and it was found impossible to cut entirely beyond it. There was a little bleeding from the cut surface near the tonsils, which was readily checked by the actual cautery. On November 3rd the patient was sitting up in bed reading the paper. On the 6th he got up. By the 8th the wound on the left side had quite healed, but the wound on the right was discharging. He was detained in the hospital in the hope that the wound would heal, but on the 14th, when he was finally discharged, the incision was still open. The patient experienced considerable relief from the operation. He lost the pain in the parts, and his speech was much more intelligible without the tongue than with it. Here it was found impossible to remove the entire disease, but the main condition was rendered much more endurable by the operation. I hear (January, 1883) that the epithelioma is now rapidly growing again and is beginning to invade the neck below the right side of the lower jaw.

Gordon-square, W. C.

ON THE USE OF CONCENTRATED SOLUTIONS OF SALINE CATHARTICS IN DROPSY.

By MATTHEW HAY, M.D.,

Demonstrator of Practical Materia Medica in the University of Edinburgh.

In the course of an investigation of the physiological action of saline cathartics, now in course of publication in the *Journal of Anatomy and Physiology*, I examined the effect of the administration of a saline cathartic on the concentration of the blood,¹ and I succeeded in demonstrating from experiments on man and the dog that, if the salt be

¹ Vol. xvi, p. 430.

given in the form of a concentrated solution when the alimentary canal of the animal contains little or no fluid, it produces an almost immediate and very decided concentration of the blood, owing to the blood becoming deprived of a large amount of its water through the intestinal secretion which the salt excites; if, however, the salt be given dissolved in sufficient water, or if the alimentary canal contain sufficient fluid at the time of the administration of the salt, no such concentration of the blood occurs. In the former case the hæmatic concentration is very considerable, and is very quickly produced. It reaches its maximum within half an hour after the ingestion of the salt; and is so marked that after giving three-quarters of an ounce of sulphate of soda dissolved in three ounces of water to a man, whose alimentary canal must have been practically free from fluid, I found that the number of blood corpuscles in each cubic millimetre of his blood rose from about 5,000,000 to 6,790,000. An almost similar result was obtained with a dog. This excessive state of concentration does not last very long. In from one to one and a half hours after the administration of the salt it begins to decline, and continues to do so until at the end of about four hours the concentration is reduced to the normal. This reduction is effected not by the absorption of fluid from the intestines, but by the abstraction of lymph and other fluids from the tissues, and the quantity thus abstracted must be very large. These alterations of the volume of the blood take place apparently without any corresponding change of the blood-pressure. The blood, therefore, would appear to abstract the tissue fluids in virtue solely of its concentrated condition, and, in the nature of its action, to behave somewhat like a sponge. The presence of the salt in the blood may also influence the tissue fluids by acting on them endosmotically. Some hours after the administration either of a concentrated or of a dilute saline solution the blood undergoes another concentration, less in degree than the first, but continuing for the greater part of the day. This second concentration is evidently due to the diuretic effect of the absorbed salt. Doubtless, during this period also, as during the first concentration, the tissue fluids are being drawn upon.

From these remarks it will be readily understood how that a concentrated solution of a saline cathartic ought to prove of considerable service in certain cases of dropsy, where, owing to the great accumulation of transuded serum in vital parts and elsewhere, there is imminent danger to life and an urgent need for an immediate and active removal of a portion of the transuded fluid. In such cases the value of saline and other active cathartics has long been appreciated, but I am not aware that use has been made of the more powerful action of a concentrated saline cathartic. It removes the dropsical fluid by two channels: by the intestines and by the kidneys. No other purgative has this double action. It is questionable, also, if any other purgative acts so rapidly in reducing the fluids of the blood. This is of the greatest importance in certain critical cases of dropsy. It is almost perfectly certain that no other purgative excites intestinal secretion so powerfully, and at the same time produces so little irritation of the intestinal mucous membrane and so little disturbance of the body generally. This is an additional recommendation for the employment of the concentrated saline. The diluted salt, the form in which it is always given, has practically, in so far as it effects dropsical fluids, the action only of a diuretic. Based on these considerations, I have made several trials of the concentrated salt in suitable cases of dropsy, and in most of them with very satisfactory

results. It is sufficient for my present purpose to give details of one of these cases.

J. A—, a young lad, aged ten, had been an out-patient of the Edinburgh New Town Dispensary for over a year, when, as one of the physicians to the dispensary, I was asked to visit him. He had been suffering for several years from heart disease. I found him propped up in bed, being unable to lie down, and showing signs of great distress. His breathing was rapid and shallow, and he was suffering from great dyspnoea, with frequent coughing. There was a well-marked ascitic distension of the abdomen and general anasarca, observable especially in the lower limbs. A loud mitral regurgitant murmur could be distinctly heard over the whole of the front of the chest. The pulse was rapid, small, and weak. An abundance of soft râles, audible all over the chest, especially towards the base of the lungs, indicated a pronounced œdema of these organs. The dyspnoea was so great that he sat with his arms straight and almost perpendicular, and with the hands pressed on the bed, elevating and fixing the shoulders to bring the extraordinary muscles of respiration into play. He had been treated previous to my seeing him with almost every variety of renal and cardiac stimulant, and at intervals with cathartics. At the time I visited him, besides some medicine to relieve the cough, he was having iron and digitalis several times a day. In spite of this active medicinal treatment, his condition was gradually becoming more serious, and the dropsy and breathlessness were increasing. The administration of a saline cathartic, dissolved and diluted in the usual way, had been tried, it so happened, two days before I saw him, but its action was attended with only slight relief. As I thought this a suitable case for the use of the concentrated saline, I ordered that he should have as little as possible of food and liquids during the night, in order to free the alimentary canal from digestive juices or other fluids, and permit of the full action of the salt, and I asked his mother, who was nursing him, to give him next morning three-quarters of an ounce of sulphate of magnesia dissolved in two tablespoonfuls of water, no water to be given afterwards. The result exceeded my expectation. When I called next evening, the patient was lying quietly sleeping in his bed. The anasarca was greatly diminished, and the dyspnoea had almost entirely gone, and his breathing was much slower. The pulse was also less rapid, and the pained, anxious expression of his face had vanished. His mother told me that she had given him the salt as I had directed, and that in less than an hour afterwards the purgative action of the salt manifested itself, and there were repeated evacuations in the course of the next few hours; on each occasion the water seemed to "gush" from him, and he passed an unusually large quantity of urine. There evidently had not been merely a removal of so much fluid from the blood and tissues as was necessary for the usual dilution of the salt within the intestines, but the sharp, sudden withdrawal of fluid from the tissues by the concentrated blood had initiated a movement of the fluid into the latter, which had continued for some hours after the direct action of the salt and the blood had ceased, and until the tissues were in great part rid of their superfluous liquid. Next day I was pleased, on entering, to find him on the floor amusing himself with the other children, and looking perfectly comfortable and happy, and, except for his wasted and pallid features, showing little evidence of having been quite recently so dangerously ill. I was told he had not felt so well for five months before. I continued to see him for a month afterwards, during which time he resumed taking the digitalis and

iron, and throughout this period he had no return of the dyspnoea, and the dropsy was comparatively trifling. Owing to the removal of the family afterwards to England, I obtained no account of his further progress. The benefit of the concentrated purgative was in this case very striking, and, perhaps, more so than in any other case in which I used it. The conditions necessary for the successful administration of the salt are that the nature of the dropsy should be such as to permit of the full action of the salt. I have found it more useful in general dropsies than in local dropsies, and of general dropsies most beneficial in those dependent on a stasis of the circulation, as cardiac dropsy. The cases in which I have employed it are, however, as yet too few to warrant me in making definite generalizations. The other requisite conditions are that the alimentary canal, by the previous abstinence of the patient for some hours previously from food, and especially liquids, should be allowed to become as free from fluid as possible, and that the salt should be administered along with the smallest possible quantity of water. Sulphate of magnesia, on account of its being soluble in less than its own weight of water, is one of the most suitable of the saline cathartics for this purpose. Sulphate of soda is, owing to its greater insolubility in water (1 in 4), less suitable. The alkaline tartrates and Rochelle salt do not, however, present this objection, and may therefore be found useful. The phosphate of soda and the sulphate of potash are too insoluble to be of any service.

Edinburgh.

OBSERVATIONS UPON THE BACILLUS OF TUBERCLE.

By SAMUEL WEST, M.D., M.R.C.P.,

Physician to the Chest Hospital, Victoria-Park, etc.

A CONSIDERABLE number of observations upon the presence of the bacillus tuberculosis in the sputum of phthisical patients have been already published, with a very remarkable and perhaps surprising concordance. To this record I wish to add the results of my own observations. I have examined myself at least fifty cases of phthisis, and, with those which have been examined for me, the number is much larger. They were all cases in which from physical and other signs the diagnosis of phthisis was certain. The sputum was treated by Ehrlich's method, and stained with fuchsin.

1. The bacilli were found present in every case without exception, although in a few cases they were in such small numbers as to be found only after repeated and careful examination. 2. They varied much in number in different cases, and even in the same case at different times. In some instances the decrease in number was coincident with improvement in the general condition of the patient, but this was not always so. The number appears to vary with the rate of breaking down of the lung, and is so far a rough measure of the gravity of the case, but there is no relation between the number of the bacilli and the extent of the physical signs. 3. When numerous the bacilli were separate or grouped together. In some of the most acute cases which I have examined they were separate, though existing in very large numbers. In other cases they were grouped together in twos or threes, or in large numbers, and they occurred occasionally in very large masses. As a rule, when the bacilli are in large numbers, they are also grouped together. 4. In some instances the bacilli contained bright bodies, which have been called spores, and these were most numerous in cases

of very rapid progress, but they did not occur in all the acute cases. Similar small bright bodies were often found free when the bacilli contained the spores, as if they were possibly free spores. 5. There seemed to be but little variation in the size of the bacilli either in the same case or in different cases, and I am unable to confirm the statements made by Balmer and Fraentzel that different stages of development may be traced in the bacilli in sputum, and that their stage of development is of importance in prognosis.

Besides the sputum, I have examined in some few cases also the contents of the cavities in the lungs, and have made microscopical sections of the lung itself. The bacilli are found, it appears to me, in largest number and in greatest masses, not in the lung tissue, but in the caseous material lining the walls of the cavities. This observation has been made also by Balmer and Fraentzel, and its accuracy in some cases I can confirm. It is a very remarkable and important fact, if it be established, that the bacilli develop most freely, not in the lung tissue itself, but in the walls of the cavities; and it provides an explanation of the variation in number and grouping of the bacilli in different cases, and in the same cases at different times.

Although the importance of Koch's discovery cannot be overestimated, still, from a clinical point of view, too much must not be demanded from it at present. The bacillus is found in all cases of undoubted phthisis, and is therefore a new fact confirmatory of the diagnosis; but as it is probable that it can occur in the sputum only when excavation has taken place, we may expect to find the bacilli absent in very early cases, even when, it may be, the physical signs are sufficient, together with the constitutional symptoms, to justify the diagnosis of phthisis.

If, however, it prove from histological observation that there are cases of phthisis in which the bacillus is not found in the tissues or in the cavities, its presence will then become of very considerable diagnostic value. The possibility, however, of such a discovery is not great, seeing that in the heterogeneous cases of phthisis hitherto examined the bacilli have been present in the sputum of all alike. Moreover, in some of the rarer cases of phthisis, cough and expectoration are absent for some time. Two cases of this kind I have at present under observation. Both, I believe, from the physical signs to be cases of phthisis; but in neither is there any expectoration. In such cases excavation only takes place later in the disease, and therefore no help to diagnosis will be obtained in the early condition from the presence of bacilli. Bacilli are, I think, evidence only of excavation, and increase in most cases therefore *pari passu* with the physical signs. If, however, after a time of progression the disease ceases to advance, it is possible that the number and grouping of the bacilli may give evidence of it, but the evidence will, I think, be more clearly marked in all probability by improvement in the general condition of the patient. We have, however, at present not a sufficient number of observations upon these points.

Regarding then, as I do at present, the number and arrangement of the bacilli in the sputum as evidence of active excavation of the lung, it is clear that their value in prognosis will be the same as that of excavation. They will give, it is probable, moreover, an easier means of estimating the rate of this excavation than we at present possess in the physical signs, and will prove therefore of some aid in prognosis. They will be large in number, and grouped together in cases of rapidly progressing excavation; small in number and not

grouped in cases of slowly progressing excavation; and they will, by varying with the rate of excavation, provide a measure of the present progress of the disease. The relation between the temperature of the patient and the bacilli in the sputum has not yet been fully worked out. So far as my own observations go they show a close relation—i.e., those cases, as a rule, which have well-marked hectic fever, exhibit the largest number of bacilli in the sputum, as indeed would be expected if they are a measure of the amount and rate of excavation.

In the recent debate at the Medical Society Dr. Gibbes could not have understood the purport of my remarks, or he would not have credited me with the astounding statement that I thought there was nothing more to be made out in this subject. What I did say was this: that Koch's experiments were so masterly and complete, that little more had been done hitherto by subsequent observers than to confirm the results he had arrived at; and up to the present this is unquestionably correct. The field of research which Koch's experiments have opened out is very large. Few can even guess what a crop of knowledge its cultivation will yield. No one surely would be so rash as to prophesy that it would prove barren soil. It is in giving us the first real hold of the disease in its essential nature that the value of Koch's discoveries lies. If it be true that phthisis and tubercle in all its manifestations be due to a special bacillus, the imagination hurries on to the time when the bacilli may be killed or rendered harmless by appropriate remedies, or the body be protected against the ravage of the germs of tubercle, as it is already against those of small-pox, or, in the case of animals, of anthrax.

With reference, however, to the question of the contagiousness of phthisis, this discovery introduces dangers of its own. The conclusion is so tempting that the risk arises of its being adopted without proof. Yet it seems certain, from clinical observation, that in this country, at any rate, phthisis is not contagious in the ordinary acceptance of the term. The analogy of typhoid fever and pneumonia suggests itself at once; for in both these diseases, just as in consumption, isolated cases of direct infection or contagion occur from time to time, and yet they would never be classed under the head of contagious diseases in the ordinary sense. And I quite agree with Dr. Broadbent in his observations at the Medical Society's debate, that the selection of the question of the contagiousness of phthisis by the Collective Investigation Committee was hardly judicious at the present time, unless those in charge of the investigation are prepared themselves very carefully to sift the evidence brought forward in each case before giving it the sanction of their authority.

Wimpole-street, W.

INTRODUCTORY NOTE ON THE PHYSIOLOGY OF THE CARBOHYDRATES IN THE ANIMAL SYSTEM.¹

By F. W. Pavy, M.D., F.R.S.

My last communication to the Royal Society was entitled "A new Line of Research bearing on the Physiology of Sugar in the Animal System." During the time which has since elapsed I have been actively continuing my investigations in the direction started, and the results obtained give an entirely new aspect to the whole subject of the physiology of the carbohydrates in the animal system.

Modern research has shown that, besides the well-known carbohydrate principles, such as sugar, etc., there are several dextrins distinguishable by their optical properties and their cupric oxide reducing power. From the colloidal principle starch, which has no cupric oxide reducing power, principles (dextrins) are producible by the action of ferments possessing gradually increasing cupric oxide reducing power, until maltose is reached, which constitutes the final product, and which possesses a little more than half the cupric oxide reducing power of glucose. This is one foundation point connected with the researches I have been conducting upon the physiology of the carbohydrates in the animal system. The other foundation point is that the various members of the carbohydrate group are brought into glucose by the agency of sulphuric acid and heat.

Proceeding upon these facts, and taking the cupric oxide reducing power before and after subjection to the converting action of sulphuric acid and heat, I have prosecuted investigations upon the transformation of the carbohydrates within the animal system with the result of acquiring knowledge of an altogether unexpected nature.

Hitherto what has been observed as regards the transformation of carbohydrates by the action of ferments and chemical agents, has been a change attended with increased hydration—for example, the passage of starch into the successive forms of dextrin and maltose, and cane sugar into glucose. The issue of the researches, however, which I have been conducting recently is to demonstrate the passage of carbohydrates exactly in the opposite direction by the action of certain ferments existing within the animal system. Alike in the alimentary canal, the circulatory system, and the liver, the conditions exist by which this kind of transformation is effected. From the mucous membrane of the alimentary canal a ferment is obtainable which converts (1) glucose into a body possessing the same kind of cupric oxide reducing power as maltose; (2) cane sugar into maltose, and not glucose as formerly asserted; and (3) starch either into maltose or a dextrin of low cupric oxide reducing power.

The presence of carbonate of soda modifies the action of a maltose-forming ferment, and leads to starch passing into a dextrin of low cupric oxide reducing power instead of into maltose. The portal blood contains a ferment which possesses a maltose or a dextrin-producing power, and the contents of the portal system during digestion are charged with a notable amount of maltose sometimes, and at other times a low cupric oxide reducing dextrin. After the introduction of glucose into the circulatory system I have observed the presence of maltose. The liver also contains a ferment capable, under certain conditions, of carrying glucose into maltose, and I have further witnessed, by the same kind of action as the sugars and dextrins are moved from one to the other, the conversion of a carbohydrate into the colloidal material belonging to the animal system (glycogen), which holds the analogous position of starch in the vegetable kingdom. Evidence has likewise been supplied that by an action of the same nature as that which moves the carbohydrates from one to the other in the carbohydrate group, they are, under certain conditions, carried into a body out of the group, and thence not susceptible of being brought into glucose by the converting action of sulphuric acid; and, on the other hand, under other conditions, a substance is brought into the carbohydrate group and its nature made recognizable by the converting action of sulphuric acid and its cupric oxide reducing power.

The subject as it even now presents itself is a

¹ Read at the Royal Society, April 12th, 1883.

large one, and I propose to deal with it in detail in a series of communications. The first will be devoted to that which refers to the alimentary canal.

CASE OF POISONING BY CITRATE OF CAFFEINE; RECOVERY.

By CHARLES H. F. ROUTH, M.D.

A PATIENT of mine, aged sixty-three, had been under my care for some time. He was a very sober but very weakly man, very nervous, but of very good spirits notwithstanding. He had been ailing a good deal for the last two years with headache, especially at the back of the head and round the right orbital region. There was also occasionally severe chestache, which appeared to impede his breathing sometimes; and severe backache, not interfering with his movements, but referred to the region of the kidney. Several remedies were tried—alkalies, iodide of potassium, salicine and salicylates, hydrochlorate of ammonia, bromides, guaranas, blisters behind the ears, pediluvia, etc. He continued under me from Jan. 3rd up to Feb. 20th, and was much better and stronger. There was no heart disease, but it was very weak in its action. The urine was also normal and free from albumen; sp. g. 1025. On Feb. 20th, as my patient did not improve as readily as I wished, I ordered him to take one drachm of citrate of caffeine three times a day, and a sleeping draught at night. I meant Bishop's granular effervescent citrate, the only medicinal preparation in vogue. Unhappily I did not specify this exactly, never doing so, and having always received this preparation when ordering it simply as citrate of caffeine. But unfortunately, also, the chemist who made it up supplied the ordinary citrate of caffeine pure and simple. My patient took one powder at 4 p.m.—i.e., a whole drachm. Symptoms followed immediately. Burning in throat and gullet, succeeded by giddiness, faintness, nausea, numbness, and tremors of extremities; pain and tenderness of bowels and stomach; great thirst; dry tongue. At 4.45 he was violently sick, with vomiting of digested matters, and also violent purging. Much urine was also passed. This sickness and vomiting recurred at 5.45. On leaving the closet he could scarcely walk, and had to be assisted. These vomited matters consisted also of digested matters. I was absent at the time, and having ascertained that it was the pure citrate that the chemist had supplied (for a powder was brought to me), I managed to get to my patient at 6 p.m. He was then collapsed; pulse hardly perceptible, irregular, 120; skin cold and clammy, but all his senses perfectly intact, not even headache; sensibility of skin nowhere impaired, a symptom not presented throughout. I at once administered half an ounce of ipecacuanha wine. In about a quarter of an hour he was very sick. I now administered two tumblers of lukewarm water, and waiting another twenty minutes and no-sickness resulting, I again gave two teaspoonfuls of ipecacuanha wine, and made him sick by passing my finger down his throat. He soon felt a little better, and I now gave him one drachm of animal charcoal with ammonia, and two and a half drops of nitrite of amyl. He rallied a little; so placing him near the fire, I left him for a few minutes. My son, Dr. Amand Routh, soon arrived to take my place at 7.30. The patient in the mean while had been very sick, had vomited largely, and also all or the greater part of the charcoal.—7.30: Condition as before; hands and feet icy cold; muscular tremors in hands and feet; cardiac oppression, sense of impending death.

Pupils equally dilated, indeed rather contracted. Some lumbar pain and tenderness, some aching about the masseter muscles. Ordered sinapism to heart; to put his feet in hot water; ammonia, alcohol, and nitro-glycerine.—10 p.m.: Debility and depression of spirits, as before. Pulse rather firmer, hands and feet warm; lumbar pain worse; no urine passed. Taking greasy mutton broth at frequent intervals, and half an ounce of brandy every four hours. Throat feels very sore, and has a burning sensation down the œsophagus. Organs of sense have been throughout unaffected, and the head is free from pain. To continue one drop of nitro-glycerine solution every two hours. The patient continued to improve till 1.30 a.m. of the 21st, when I left him. I saw him with my son the next morning. He complained still of feeling very ill; but he was certainly not so weak; his pulse was stronger, but the top of the head was very painful; had urinated freely. The right orbital region was also very painful. Nitro-glycerine was continued; no sickness; took milk and soda-water freely. Cold to head to relieve pain. As he complained still of a burning sensation in the mouth, I ordered ice, but this producing intense abdominal pain it was stopped. The diluent drinks with raw beef-juice were freely taken. Later the headache increased and the pain in back, both of which were relieved by mustard poultices. Later I substituted digitalis and gave up the nitro-glycerine. From time this he improved. The prostration gave way, and he complained mainly of the back. On February 24th the pulse was 80, not over-strong; urine, specific gravity 1025, no albumen, doubtfully a trace of sugar. Lumbar pain relieved by pressure, only muscular; no headache. Food mainly bread and bread-and-milk, with brandy and soda-water.

In sum, the symptoms were those of a vegetable and depressant irritant. But for the violent sickness, I think the dose would have been fatal, especially with so a weak a man. It is, I believe the only case on record of poisoning in the human subject by caffeine, and as such, is, I think, worthy of record. I am, perhaps, to blame for not having written more precisely the drug meant; but the chemist who supplied it, I think, was equally to blame for not knowing that pure caffeine in these large doses would necessarily act as a poison. It is usually said convulsions occur in these cases. Here nothing worse was observed than muscular tremors. It may be worthy of remark that the mind was and has continued unaffected throughout. This case is also instructive as showing what a very powerful agent we possess as a nervous medicine in caffeine, if it be used in proper medicinal doses.

Montagu-square, W.

ON THE SIMPLE TREATMENT OF CONGENITAL CLUB-FOOT.

By EDMUND OWEN, F.R.C.S.,

Surgeon to St. Mary's Hospital, and to the Out-patients at the Children's Hospital.

THE common form of congenital club-foot is that in which the heel is raised and the sole twisted inwards. The speculation has been ventured upon that the deformity may be the result of the adaptation of the foot to the restricted accommodation of intra-uterine life. Whether this be so or not is immaterial to the aim of this short communication, in which I shall submit that in many, if not in most, of the cases of congenital talipes equinovarus a permanent shortening of the tendon of Achilles is the head and front of the offending.

When this tendon has shortened to the utmost in the elevation of the os calcis it can contract still further by effecting a rotation of the bone upon its antero-posterior axis, the astragalus also participating in the inversion. The natural bowing of the leg and the absence of malleolar projection upon the inner side determine that the secondary distortion of the foot shall be inwards. Probably in the early months of the compound deformity the tibial muscles have but little concern in the matter, though, if the treatment of it be delayed, their tendons have no more chance of undergoing due growth than have the bones and the pedal structures generally, and thus they may eventually require section. My reasons for advancing this view are briefly these:—1. Uncomplicated talipes equinus is by no means of infrequent occurrence as a congenital deformity, whilst simple inversion of the foot without any elevation of the heel is a rarity; and, as talipes varus is commonly associated with equinus, it appears not improbable that the inversion of the foot is but a further development of what would otherwise be an extremely common congenital deformity—talipes equinus. 2. In ordinary equino-varus the tendon of Achilles is displaced well to the inner side of the vertical median plane of the ankle-joint, as if, having expended its energy in raising the heel, it had finally imparted to it a definite inward twist; and this condition is to be made out even when there may be no great amount of contraction of tibial tendons. 3. In many cases of slight equino-varus, when one has been hesitating as to whether or not the tendons lying against the internal malleolus should be divided before that of the calf muscles, and has eventually decided against their divisions, on cutting through the tendon of Achilles all the inversion of the foot has disappeared. 4. A prolonged and intimate acquaintance with the employment of the plaster-of-Paris bandage has shown me that in many instances of the twofold deformity of infants division of the tendon of Achilles is the only cutting operation required.

If the theoretical parts of the foregoing sentences be deemed unsatisfactory, a total disregard of them will in no way interfere with the excellent working hypothesis with which I venture to associate them. And here I would remark that the "simple treatment" which I am about to describe in no way refers to those varieties of slight deformity which one has been accustomed to see effaced by massage or manipulation, or by the education of a splint of tin; nor, on the other hand, does it refer to those deformities of later childhood in which all the structures concerned have become rigid, misshapen, and displaced.

In the ordinary course of dealing with an infant's foot in which the heel was firmly elevated and the sole faced directly inwards one or more of the tibial tendons would be divided, and after the lapse of a few days the foot would be secured in a Scarpa's shoe, for the correction of the inversion. When this first step in the operation had been accomplished the second would be taken, which consisted in the section of the tendon of Achilles; and when the slight wound in the skin had become securely mended the heel would be gradually brought down by means of the working of a cog-wheel at the ankle. Subsequently through weeks or months precautions had to be taken to provide against a relapse. Those who have had much to do with Scarpa's shoes will probably agree in this, that, excellent as they are, they are costly; that in hospital practice at least they are apt to get out of repair; that the little patient has a marvellous knack of getting his small heel from out of the depths of the shoe; that the infant requires almost daily surgical supervision; and that, even

when the greatest care is being exercised, the localized pressure of a strap is apt to excite general irritability or distress, and to excoriate the foot. Now, by substituting a properly prepared plaster-of-Paris bandage for the mechanical shoe in many cases the tendon of Achilles only need require division; and about three or four days after the little operation the foot is to be put in a thickish sock which fits it evenly and smoothly. Then, from about the line of the clefts of the toes to a few inches above the ankle, the foot is to be quickly and firmly encased in the wet plaster bandage, and immediately that the last turn is finished the foot is to be forcibly manipulated, so that as the plaster is setting it may be steadily held in a position towards flexion and eversion such as shall give cheering and definite promise of eventual cure. In three minutes or less, when the plaster has hardened, the tip of the sock should be cut off in order that the toes may be exposed to view, for if they by chance were seen swollen or congested the hardened bandage would at once be removed; but if not, the casing might be left on for two or three weeks without being touched. At the end of that time it should be removed by finding the end of and unwinding the bandage. The foot should then be rubbed with oil and again enclosed as before, only as the plaster is hardening this time the position is to be absolutely rectified. In another three or four weeks the foot may be again examined, and then put up a third time in plaster-of-Paris, or fitted with a stiff leather boot, as may be deemed expedient; when the patient lives at a distance the former course is desirable, lest the needful frictions and manipulations being but imperfectly executed a relapse follow.

As a rule the infant suffers but little discomfort after the first few hours; and I am told by those who are in a position to judge that the smooth pressure of the casing does not distress the child even during that short period as much as does occasionally the tightening of the strap of a Scarpa's shoe. Certainly in a long series of cases which have been thus treated, I have never once seen the skin sore or even threatening. The supervision after a few days have passed need entail no trouble either on the part of the surgeon or the mother. At the present moment I have hospital patients who are being thus treated in Buckinghamshire, at Woolwich, and in several other outlying places, and, having arranged that on the slightest suspicion of there being anything going wrong under the bandage I am to see the child, I am able to let the mother attend once a fortnight. In one case there was some suppuration under the skin of the calf, which was in some obscure manner due to the bandage; but the complication soon passed away and merely prolonged the ordinary course of events.

I should say that, as a rule, the plaster bandage has to be reapplied three or four times; probably much of the success attending its employment depends upon attention to the following details:—The bandages should be about two inches wide and two yards long; one and a half or two of them will be necessary. The material of which they are composed should be "cross-wove crinoline muslin," and this should be boiled before it is used in order to free it of the stiffening of size with which it has been "dressed." When it has been dried its meshes can be more easily and thoroughly impregnated with the dry plaster which is to be rubbed over each side and well up to the ends of the bandage. The plaster should be quite fresh, and of that fine quality which dentists use for their maxillary models. A most important point is that the impregnated bandages be loosely rolled, so that immediately they are put into water every

molecule of the plaster may be straightway wetted. The roller must be dipped, not soaked, in the water, and should be applied dripping wet, for squeezing it drier in the hand involves the loss of much valuable plaster from its folds or meshes, and perhaps also some slight loss of time. A little common salt should have been dissolved in the water to hasten the setting of the plaster. The whole business occupies about five minutes; and on its conclusion a handful of moist sugar in the wash-hand basin will be found of excellent service in freeing the operator's fingers and nails of the tenaciously adhering plaster.

Seymour-street, W.

ON THE TREATMENT OF DOG-BITE IN THE EAST CONSIDERED WITH REFERENCE TO THE PREVENTION OF HYDROPHOBIA.

By PHILIP S. BRITO, M.B., M.Ch.,

Demonstrator of Anatomy at the University of Aberdeen.

ACCORDING to Dr. Hecker, it would seem that hydrophobia existed at least four hundred years B.C., and as time marches onwards instances of valuable lives sacrificed to the love we bear our domestic pets will perhaps be added to the already significant list of fatalities from this disease. It is saddening to contemplate such an event, and with the hope, therefore, that my remarks may possibly help to mitigate this evil, I crave publication for them.

An old Tamil proverb has it "that the bite of the dog needs the use of the sandal." (The sandal, I may inform my readers, is an open shoe worn in hot countries, and may, perhaps, be likened most to an ancient Roman "soccus.") This proverb grew probably out of the treatment adopted in cases of such injuries. The first thing done, and that as soon after the bite as possible, is to chastise vigorously with a sandal the part bitten. This remarkable procedure puzzled me not a little, and I was inclined to ascribe it to a charm, and therefore to discredit the rest of the treatment. But a depth of philosophy seems to underlie it. For on mentioning the circumstance to a professional brother he suggested what seems the true significance of the habit: the effect of such rough treatment being to make the wound bleed freely, and to ensure thus the removal of a portion, at all events, of the virus. It may be asked, Why use a sandal in preference to any other article? I believe it is from the readiness with which it is procurable, as well as from the firm purchase it affords the chastiser from its peculiar shape. Meanwhile some leaves of the *Murungai* (Tamil), *Murungah* (Singhalese), or "drumstick" tree,¹ are beaten up with a little chunam² (caustic lime), and applied to the wound, which is then bandaged. With this treatment the wound usually heals kindly. The interest of all this centres in the consideration whether we are not dealing with some constituent of the leaves which may modify or counteract, in short act as an antidote to, the poison contained in the saliva. Reliable statistics, and still better, reliable experiments, can aid us here. In the interest of science and suffering humanity would our medical brethren in the colonies, to which this tree is indigenous,

¹ I regret that I am not in a position just now to give its technical name. My readings of Emerson Tennent's Ceylon and allied works were attended with equal unsuccess. It is probably one of the cassias. Even for this information I am indebted to the courtesy of Dr. Trail, Professor of Botany, who, from the very general description I was able to give of the tree, imagines it to belong to that family.

² Lime obtained by the calcination of shells (Tennent's Ceylon).

and where happily they yet enjoy untrammelled the blessed freedom of vivisectional investigation, work out the details of the outline herein presented, and settle how far this treatment, so common in Ceylon and parts of India, is worthy of adoption or rejection?

Aberdeen.

ON A CASE OF CONGENITAL CONTRACTION OF THE KNEE-JOINTS WITH DOUBLE TALIPES; TENOTOMY, AND SUBSEQUENT EXTENSION WITH MARTIN'S RUBBER BANDAGE.

By T. HENDERSON POUNDS, M.R.C.S.

E. P.—, aged twelve years, was first brought under my notice in January last. She then presented the following deformity:—Both the knee-joints were contracted, the legs being flexed on the thighs almost at right angles. There was also a double talipes varus. The usual method of progression was on "all fours." On being suspended vertically from the axillæ the tips of the toes only touched the ground. The hamstrings offered a firm resistance to any attempted extension, and very severe reflex contractions ensued upon such an attempt. Finding the muscles on the weakened side responded slightly to the faradaic current, at the parents' request an operation was decided upon. Accordingly at the end of January last I operated on the right limb, dividing all the hamstrings and the popliteal fascia subcutaneously; this latter was distinctly ridged up into vertical fibro-cartilaginous bundles, which gave way on division with audible crepitus. The talipes was also treated at the same time by division of the tendo Achillis and tibials. The limb was put up in plaster of Paris, and left undisturbed for six days. The plaster was then taken off, the limb washed, only slightly extended, and a back splint applied at the knee. A Martin's rubber bandage was then wound round the instep over a stocking, well padded and brought up "on the stretch" on the outer side of the limb; this was fixed above the knee and then used to bind down the knee to the splint, each turn of bandage being put on the stretch; the knee was well padded, a thick pad being placed over the patella. The limb was thus brought gradually into its normal position, the talipes being remedied at the same time. The left limb was operated on a month later, with the same after-treatment. The strain of the antagonistic muscles being taken off, the limbs developed rapidly, the calf of the right limb within the month gaining two inches in circumference. Faradism, frictions of the limbs, "massage," and later on the application of a permanent apparatus with extensions at the knees and ankles, completed the case. The child can now walk a quarter of a mile without stopping, and with little support, although the limbs give to a certain extent at the knees from the want of sufficient power in the extensors.

EXTENSIVE INJURY TO ABDOMEN AND THIGH; DISARTICULATION OF HIP.

By JOHN FOX, M.D., M.R.C.S.

ABOUT twenty-two years ago a young lad was brought to the Greenock Hospital, having sustained a most severe injury while attending at a circular saw in a wood yard. The destruction of the soft parts around the left side of the abdomen

and upper and anterior portion of the left thigh was so extensive and serious that there was no alternative left but to perform disarticulation of the limb at the hip-joint. This operation I performed carefully and slowly, and dressed the part with moist lint, straps, and plenty of support with cotton bandages.

The patient progressed satisfactorily for six weeks, no other application than the water dressing, already described, being used. In the course of one month and three weeks from the time of admission I thought proper to give him change of air and intercourse with his relatives, and accordingly I ordered him home, where I paid every attention to him for five weeks. The patient was walking about the house on crutches in less than three months after the operation, and shortly after I had the extreme gratification of seeing him in the street with the intention of going to visit a kind friend.

The great peculiarity of this case is that after the expiration of twenty years his spine is as straight and level as if no operation of the kind had been performed on him. His general health has been good, without the slightest interruption to any function, and he has not suffered from any ailment, not even trifling, since he was under my professional care. My very esteemed friend, Mr. Prescott Hewett, of Mayfair, saw him about six years ago, and, though much pleased with his then condition, warned me to look out for curvature of the spine, as the superincumbent weight would necessarily produce such a condition. My brother-in-law, the late Dr. Henry Davis, of Putney, also saw and carefully examined the spine subsequent to Mr. Hewett's visit, and he pronounced curvature as inevitable in the course of a few months. I had an opportunity of seeing my former patient within the last few days, and made it a point to examine him carefully; the condition of the man far exceeded my most sanguine expectations, the result being quite contrary to the grave anticipations of Mr. Hewett and the late Dr. Davis.

I may mention that from the day of admission to the hospital to the time of dismissal there was not one unpleasant symptom; on the contrary, the progress of the case was steady and highly encouraging. The ligature (silk) came away on the fiftieth day, and the union was complete in the course of a few days after its removal.

Successful cases of this kind of operation are so few, particularly in Scotland, that it ought to encourage surgeons, even where appearances are against the hope of ultimate success.

Greenock.

SPINAL MENINGITIS IN A CHILD FOLLOWING SPINAL CONCUSSION; RECOVERY.

By WILLIAM HENRY DAY, M.D.,

Physician to the Samaritan Hospital for Women and Children.

M. T—, aged twelve, a well-made, healthy-looking girl, was admitted into the Samaritan Hospital, Nov. 18th, 1881, suffering from the effects of concussion of the spinal cord. Three months before admission she jumped, it was said, from the top of a heap of dirt, and on touching the ground struck the lower part of the spine, directly over the sacrum, her feet turning upwards at the same time, as she glided some distance along her back. I think there is little doubt, from what the girl said, that she was stunned at the time of the accident, as she was told she did not answer in reply to questions put to her. This is an interesting point, as in violent falls on the lower end of the spine the

brain sometimes suffers from slight concussion. With the assistance of two school-fellows she got up, and was led home with difficulty. She suffered sharp pain over the seat of the accident, but, after remaining in bed two days, she resumed attendance at school. After two days as she could not sit up without pain at the bottom of the back, she gave up attempting to walk, and took to her bed till the time of her admission into hospital. On examination there was a distinct fulness over the sacral region, and the coccyx was tender, though on insertion of the finger into the rectum no fracture or dislocation of that bone could be detected. The whole spine was curved, owing no doubt to the position she had assumed in bed. She complained of pains down both legs; there was an inclination to draw them up, and there was a sensation of pins and needles, as if they were going to sleep. The patient walked with the face looking to the ground, the shoulders and head bent forward, and the nates prominently projected. On applying a needle to the legs, sensation in the right limb was much less than in the left. It was not recognized at four inches and a half apart as two pricks; in the left it was recognized at two inches. The temperature was normal, the tongue clean, the pulse quiet, and the bowels were regular. The urine was of a pale straw color, alkaline, sp. gr. 1020. The child was kept in bed, a light nutritious diet ordered, and the following draught was given three times a day:—Iodide of potassium, two grains; tincture of belladonna, five minims; compound tincture of cinchona, half a drachm; to half an ounce of water.

On Dec. 1st Mr. William Adams was kind enough to see the patient and to report that the case appeared to be a genuine example of spinal concussion, followed by inflammation of the membranes, which might extend to the substance of the cord, but as yet there was no myelitis. He recommended repeated small blisters to the spine in the lumbar region, reaching as high as the eighth dorsal vertebra, so as to relieve congestion about the lumbar enlargement, and a moderate amount of counter-irritation kept up. He thought absolute rest in bed with this for a few months would arrest further mischief. Mr. Adams further wrote, "I believe you are quite right in suggesting chronic inflammation with effusion, and the case should be very carefully watched for a long time, as possibly Pott's disease of the spine may become developed, or paralytic symptoms, preceded by pain; starting and drawing up of legs may show the extension of inflammation to the substance of the cord. Special symptoms were well marked at the time of the fall, as she could not get up, and was obliged to be carried home."—Jan. 20th, 1882: She is better, and makes no complaint of tingling in her legs; the puffiness and tenderness at the lower end of the back are less, but she cannot lie straight in bed. Urine clear, acid, non-albuminous. The blistering was repeated.—Feb. 10th: Has greatly improved since last report. She moves more easily in bed, and the pain and puffiness in the back are less. There is still some tenderness over the lower lumbar and sacral region, and she complains of occasional sensations of pins and needles, chiefly in the right leg. The medicine was omitted.—March 3rd: During the last week she has been walking about the ward for a short time; she is more upright, and the sensation of pins and needles has departed.—March 19th: She left the hospital with instructions to be kept lying on her back for three months.—Jan. 1883: A report from her friends reached me that she laid on her back as directed for three months, and then went to school. She is quite straight, and can walk well without limping, or feeling pain in her back

or limbs. No spinal support has been worn throughout. No one would know from her gait that her back had been affected.

ON A CASE OF COMPOUND COMMUNUTED FRACTURE OF THE SKULL; TREPHINING; RECOVERY.

By A. D. MURRAY, M.B., M.C.

ON October 26th, 1882, I was called to see H. G—, a man about thirty-eight years of age, who had been thrown out of a cart. I found him suffering from a downward dislocation of the shoulder and a severe wound of the head. After reducing the dislocation I examined the head, and found that there was an extensive fracture of the parietal bone, a triangular fragment being deeply depressed and driven under the sound bone. From the depression fissures could be felt running downwards for about an inch and a half towards the eye and ear. The man had very slight symptoms of concussion and none of compression; but looking at the amount of depression I resolved to trephine without waiting for symptoms to come on. The operation was performed in the usual way. A little more than half a circle was removed from the sound bone above the apex of the triangular depressed portion, and after a corner had been removed by means of the saw the piece was easily lifted out; a clot was found under this. The middle meningeal could be seen pulsating at the lower corner, but was uninjured. Some fragments were taken away, the wound dressed with carbolic oil, and washed frequently with carbolic spray. The man made an excellent recovery, never having had a bad symptom.

I think that this case points strongly to the advisability of trephining at once in compound comminuted depressed fracture of the skull without waiting for symptoms of compression. The operation does not add to the patient's danger, and may, in all probability, be the means of preventing serious complications. I feel sure that had the sharp point of bone remained pressing on the membrane serious irritation would have followed, and that the operation would ultimately have had to be performed under much less favorable circumstances.

Rickmansworth.

SEVEN CASES OF COLOTOMY, WITH REMARKS.

By GEORGE ELDER, M.D.,

Surgeon to the Hospital for Women, Nottingham.

CASE 1.—Three years ago I saw in consultation a case of absolute intestinal obstruction due to malignant disease of the rectum, when colotomy was advised and performed with the result of giving immediate relief to the patient's suffering and prolonging life for thirteen months. During the last two years six other cases have occurred in my own practice, of which the histories are briefly as follows:

CASE 2.—The patient was a woman, between thirty and forty years of age, suffering from syphilitic stricture and ulceration of the rectum. As a hospital out-patient she had had both general and local medical treatment without avail, and with the view of diminishing the intensity of her sufferings, if nothing else, the operation was performed on January 29th, 1881. Three weeks subsequently she was discharged—a gainer in comfort, flesh and strength. From time to time she appears amongst

my out-patients, very different from the prematurely old-looking, suffering woman of two years ago.

CASE 3.—On February 10th, 1881, I performed colotomy upon a woman with a recto-vaginal fistula due to syphilitic diseases; an opening into the descending colon was made. The exceeding debility of the patient, induced by a recent acute illness, made the case a very unpromising one; but the loathsome nature of her rectal disease, with its ever-present depressing effect upon her, decided me to operate. Her recovery was fairly good, and on March 16th she left the hospital, entirely relieved of her sufferings. On Dec. 9th of the same year she died, as I was informed, from exhaustion due to the original disease.

CASE 4.—On February 17th, 1881, left colotomy was performed upon a lady from Sheffield who had been under me at various times for several years suffering from many of the phases of syphilis. Mercury locally and constitutionally, the iodides in very large doses (one drachm and a half daily), medicated bougies, etc., had been long and fairly tried, until at length her sufferings from the constant tenesmus became so intense that she implored me, even at the risk of losing her life, to relieve her. Fifteen days after the operation she was able to undertake the journey home, and in a letter which I had from Mr. Pye-Smith, of Sheffield (to whom the patient applied last year to have the artificial anus closed because of its discomfort), he informed me that before making this attempt the rectum was examined, and the ulceration by lapse of time and absence of faecal irritation was found to have healed. He concludes his letter by saying that doubtless her life has been prolonged and pain alleviated by the colotomy.

CASE 5.—On May 19th, 1881, I performed the operation on a male with malignant rectal disease. The local distress had caused him to seek relief. Fifteen days after the operation the patient returned to his home, ten miles off, and when heard of last summer he was following his occupation of engine tenting, and although feeling acutely the disagreeables incident to an artificial anus, still free in a great degree from the distressing and almost constant bowel pains.

CASE 6.—On June 9th, 1882, in a case of pelvic tumour, which had developed malignancy, and almost entirely occluded the bowel, I formed an artificial opening. The patient had become so exhausted, from the local distress, coupled with the ravages the disease had inflicted on her general nutrition, that when the operation was agreed to death seemed imminent. The shock of the operation almost killed the patient, and although she lived for sixteen days perfectly freed from pain, still the wound never put on healing action.

CASE 7.—Four days after the above case, I again did the operation on a woman between sixty and seventy years of age for malignant rectal obstruction. Her recovery was uninterrupted and rapid, and relief from suffering most marked. The other day she called on me, grateful for what had been done for her.

Remarks.—Up till date these seven cases complete my experience of colotomy. In all the left lumbar operation was performed and the incision was oblique, running from the margin of the last rib across the quadratus lumborum to and in front of the anterior superior iliac spine. No particular difficulty was experienced in any of my cases, and the loss of blood was but trifling. In one instance a fold of subperitoneal fat so simulated the flaccid bowel that I had actually transfixed it before finding out my mistake. There is a danger of making the incision too far forward. This I did in Case 6 and in consequence wounded the reflected perito-

neum, but no harm was done the patient thereby. Carbolized catgut was used in my first two cases to fix the edges of the opening to the skin, but because of its solution before firm union had taken place it was abandoned for Chinese silk. Colotomy is not practiced so often as it ought to be. By diverting the feces and so giving rest to diseased parts it may be directly curative in its action, as illustrated by Case 4. For such cases its more general adoption would prove a great gain in the treatment of cases which otherwise are intractable to treatment. The repugnance which patients frequently manifest even at the thought of such an operation would in great measure be removed when the temporary character of the artificial opening was explained, and the strong reasons for its production. When cure is altogether out of the question, owing to the malignant nature of the disease, we can replace intense, even in many cases incessant, pain by comparative comfort, and, unless the operation is delayed too long, prolong life. This is abundantly shown in the cases above recorded, and by an operation the mortality from which is very small. If patients suffering from malignant disease were seen sufficiently early, a combination of colotomy, as a temporary measure until healing of the parts had taken place, and excision of the diseased portion of bowel would offer the best chance of ultimate recovery. But unfortunately such patients as a rule come too late.

Nottingham.

ON THE COMPARATIVE INUTILITY OF ANTISEPTIC INHALATION AS AT PRESENT PRACTICED IN PHTHISIS AND OTHER DISEASES OF THE LUNGS.

By ARTHUR HILL HASSALL, M.D. Lond.,

Late Senior Physician of the Royal Free Hospital; Founder of and Consulting Physician to the National Hospital for Consumption and Diseases of the Chest.

THE title of this communication will doubtless be a surprise to the advocates of antiseptic inhalation in phthisis and other diseases of the lungs. It has appeared to me that the practice of such inhalation, which is now so much in vogue, has not been shown to rest on any true or scientific basis or foundation, and further that the clinical evidence in its favor is so far singularly weak, notwithstanding the publication of a number of cases affirmed to have benefited thereby. Under these circumstances I have been led to institute a series of experiments and observations with a view to test the efficacy of antiseptic inhalation in the class of diseases mentioned, and I will now proceed to relate the results. The principal antiseptic substances used are phenol, commonly known as carbolic acid, employed much more frequently than all the others, and to which therefore the most importance is attached; creasote, which ranks next; thymol, now coming into more general use; and iodine. Phenol, or carbolic acid, C_6H_5O , has the following properties:—It melts at $107.9^{\circ} F.$ to a colorless fluid, which is slightly heavier than water. When pure it boils at $359.6^{\circ} F.$, and distils without decomposition. The crystals readily absorb moisture from the air; a hydrate, C_6H_5O, H_2O , containing 16.07 per cent. of water, and melting at $63.0^{\circ} F.$, being formed. One part of the absolute acid requires 10.7 parts by weight of water for complete solution. The solutions do not redden litmus, but the acid forms definite salts with strong bases. It is miscible in all proportions with alcohol, glacial acetic acid, and glycerine; also (when anhydrous) with ether, benzene, carbon disulphide, and chloroform.

Smell and taste are much less marked in the pure than in the commercial acid. It coagulates albumen, is a powerful antiseptic and poison, and acts as a caustic on the skin. Nothing is said in books about the volatility of phenol at ordinary temperatures, yet from the powerful odor emitted one would be led to infer that it must be volatile to some small extent. With a view to test this point the following experiments were made: 0.5 gm. exposed uncovered to the air, at a temperature of about $48.2^{\circ} F.$, lost .0035 gm. in two hours, and .0071 gm. in four hours; 0.5 gm., placed under a bell-glass and in air dried by sulphuric acid, lost .0025 gm. in two hours, and .0054 gm. in four hours. These experiments show that the volatility of phenol at ordinary temperatures is exceedingly slight; it increases, however, as shown by some further experiments, which it is not necessary to detail in this place, in proportion as the temperature is raised. One-half gramme of phenol, or 500 milligrammes, equal to about 7.70 grains, was dissolved in water, and placed on the sponge of one of Mayer and Meltzer's cellulose oro-nasal inhalers, and the inhalation was continued for one hour. Of the 500 milligrammes taken 412 were recovered from the sponge, showing a deficiency of only 88 milligrammes. In the second and third similar experiments the amounts recovered were 413 and 458 milligrammes respectively, showing a loss of only 87 and 42 milligrammes. Thinking that the volatility of the carbolic acid would be aided by dissolving it in some more volatile substance than water, experiments were next made with spirits of wine and spirits of chloroform as the solvents. In three trials with half a gramme of carbolic acid, equal to 500 milligrammes dissolved in alcohol, the amounts still retained in the sponge at the end of the inhalation were 442, 485, and 480 milligrammes respectively, showing deficiencies of 58, 15, and 20 milligrammes only. The results of two experiments with spirits of chloroform as the solvent were similar, the amounts recovered being 485 and 495; in the one case 15 milligrammes had disappeared, and in the other five only. It thus appears that the solution of the phenol in alcohol and chloroform in place of increasing really lessens the volatilization.

I may now state that the phenol was quantitatively determined by the very delicate and accurate process of M. T. Chandelon. It is difficult to suppose that the small quantity of carbolic acid which disappeared during the several inhalations could exercise any marked effect in the alleviation or cure of such a malady as phthisis, even if the whole quantity made its way to the seat of the disease, but this it certainly does not do; some is lost in the respirator itself, more in the manipulations necessary to remove the remaining phenol from the sponge, but a still larger amount is absorbed by the skin of the lips and the mucous membrane of the nose, mouth, and fauces; so that it becomes extremely doubtful whether any portion of this antiseptic ever reaches the air cells of the lungs. This doubt is greatly strengthened by the fact that the sputa in cases of phthisis brought up shortly after inhalation never, so far as my experience goes, smell of carbolic acid; neither have I ever found that acid present in them in any notable quantity. Another fact corroborative of this view may here be cited. The air expired during the inhalation of the carbolic acid was passed through distilled water which was afterwards tested for the acid, the faintest trace only being discovered.

The next antiseptic experimented with was creasote. No volumetric chemical process being known for the quantitative estimation of this compound, the gravimetric method had to be pursued, which,

however, furnishes results sufficiently precise for the purpose. Creasote, as is well known, is the product of the distillation of wood tar; it is a very variable admixture of several phenol-like bodies; guaiacol, $C_8H_8O_2$, boiling at $392^\circ F.$; creasol, $C_8H_8O_2$, boiling at $422^\circ F.$; phlorol, $C_8H_8O_2$, and methylcreasol, $C_8H_8O_2$, being the chief constituents. The composition of creasote varies with its origin. Carbolic and cresylic acids occur in pine wood creasote. Guaiacol predominates in Rhenish creasote. Morson's English creasote consists chiefly of creasol, and boils at about $422^\circ F.$ Creasote is sparingly soluble in water, possesses a smoky taste and smell, and is a powerful antiseptic; it preserves animal matters without causing disintegration, as phenol is apt to do, and is less powerfully caustic than the latter. Creasote is miscible in all proportions with alcohol, ether, benzene, chloroform, acetic acid, etc.; like phenol, with which it is often adulterated. 0.5 gramme exposed to the air under the same circumstances as the phenol lost .0090 gramme in two hours, and .0113 in four hours; another 0.50 gramme placed under a bell-glass with sulphuric acid lost .0084 in two hours, and .0106 gramme in four hours. It thus appears that creasote is somewhat more volatile than phenol, but still is of very slight volatility. From half a gramme or 500 milligrammes of creasote, inhaled with water for one hour, 430 milligrammes were recovered, the creasote being dissolved out of the sponge by means of alcohol. From the same quantity of creasote dissolved in spirits of wine there were recovered in the first experiment 406, and in the second 410 milligrammes. While lastly, from the same quantity of creasote dissolved in spirits of ether there were obtained 416 and 406 milligrammes respectively. These experiments show, as was the case with the phenol, that upwards of four-fifths of the creasote used remain in the sponge of the inhaler, while of the remaining small quantity some is lost in the inhaler itself, some is absorbed by the mucous membrane of the nose and mouth, while part is lost during the evaporation of the spirits of wine and ether employed as the solvents of the creasote.

I will now detail the results of the experiments with thymol. Thymol, $C_{10}H_{14}O$, is the camphor of oil of thyme, and is a solid crystalline substance with a pungent taste and aromatic odor. It melts at $111.2^\circ F.$, and does not easily resolidify unless touched by a solid body or a crystal of thymol. It boils at from 428° to $446^\circ F.$; it is slightly heavier than water; in the fused state rather lighter. It is but little soluble in water, requiring about 1,000 parts for solution. Thymol is a powerful antiseptic, its preservative power being ten times as great as carbolic acid, according to Bucholz, and four times as great according to Willmott. It acts as a caustic on the lips and mucous membrane, but does not irritate the skin like carbolic acid. It is soluble in ether, strong acetic acid, and in its own weight of rectified spirit, but is very sparingly soluble in glycerine. 0.5 gramme gained .0003 gramme at the end of two hours, and the weight had not altered after four hours. In an experiment in dry air under a bell-glass there was also no alteration of weight, even at the end of four hours. These figures show that thymol is not in the least volatile at ordinary temperatures. There were recovered after an hour's inhalation in the first experiment 412, and in the second 466 out of the 500 milligrammes employed, and which were dissolved in ether. From the same amount of thymol dissolved in spirits of wine there were obtained 450 and 466 milligrammes. It is therefore scarcely possible to conceive that this antiseptic can, as at present employed, exert any beneficial effect.

The last antiseptic of which trial was made was iodine. Iodine volatilizes at ordinary temperatures in the open air, especially in the presence of moisture; it melts at $224.6^\circ F.$, and boils at from 347° to $356^\circ F.$; it is very sparingly soluble in water, 1 in 7,000 parts only, but is much more soluble in alcohol and ether, and in aqueous solutions of the soluble iodides. It resembles closely chlorine and bromine in its chemical relations. 0.5 gramme exposed to the air lost .0124 gramme in two hours, and .0178 gramme in four hours; 0.5 gramme in dry air under a bell-glass lost .0103 gramme in two hours, and .0145 gramme in four hours. The only experiments made with iodine were the following, but, as will be seen, these were very conclusive:—200 milligrammes of iodine were dissolved in 10 cubic centimetres of spirits of wine, and of this mixture 1 cubic centimetre containing .020 of iodine was placed on the sponge of the inhaler, with a little alcohol added, and inhaled for an hour. A similar experiment was made with spirit of ether as the solvent. The vapor given off was at first pungent and stinging to the mucous membrane of the nose and mouth, but on examining the sponge at the end of the hour all but a trace of the iodine was found to have disappeared. In iodine, therefore, we really have a volatile agent to deal with, and hence it might be presumed that it did, in fact, make its way into the lungs. This conclusion, though apparently warranted by the disappearance of the antiseptic during inhalation, is not confirmed by further observation.

When testing the saliva and mucus of the mouth and throat on the completion of the inhalation with a solution of starch, I noticed that the color of the starch was unchanged, proving the absence of free iodine. On applying, however, an acid to the mucus, the blue color was abundantly developed, showing that very much of the iodine inhaled, and possibly the whole of it, had become converted into an iodide, in which transformation it loses entirely its antiseptic properties. This is an interesting and important fact, not only in relation to the subject now under consideration, but in other ways. Thus, for one thing, it shows how useless it is to administer free iodine as a medicine. Again, it should be known that when, as is frequently the case, carbolic acid and iodine are inhaled together, a strong chemical action is set up between them, whereby probably the antiseptic properties of both are impaired. In the case of iodine, then, evidence is also wanting to show that this antiseptic does really make its way into the lungs. Now it may be urged that if the inhalation of the several antiseptics had been continued for a longer period than an hour, the result would have been different—that is to say, that more of them would have been inhaled. In order to test this point, the inhalation of carbolic acid was continued for two hours in three experiments with the following results:—Of the 500 milligrammes taken, there were recovered by Chandelon's process 410, 400, and 390 milligrammes respectively, thus showing only a very moderate increase, quite insufficient to affect in any material manner the general results arrived at. Even had the amount inhaled been much greater, it would by no means have followed that a proportionate increase of the antiseptic was to be found in the lungs. Supposing a small quantity of any of the antiseptics really reaches those organs, it is not to be supposed that it remains there for an indefinite time, and goes on accumulating as long as the inhalation is continued. The action of the absorbents would doubtless come into play, and the antiseptic which was inhaled the first hour would become removed by absorption during the second hour. Again, it

might be urged that if smaller quantities of the antiseptics were placed in the inhaler, the proportionate volatilization would be greater. 250 milligrammes of phenol in water were sprinkled on the sponge of the inhaler, and inhalation continued for an hour, at the end of which time 234 milligrammes were recovered from the sponge, showing a smaller, and not a larger, proportionate loss.

It will, I think, now be readily acknowledged that the title of this communication was fully warranted by the facts and evidence produced; indeed, it appears to me that a stronger title would have been justified. The subject of antiseptic inhalation in diseases of the lungs is a very important one, and is by no means exhausted in the present communication. I am continuing my observations and experiments; but so far I have come to the conclusion that the most practical method of accomplishing the object in view is by means of an inhalation chamber. There are many difficulties in the way of the construction of such a chamber, and many points would have to be attended to; but the difficulties are by no means insuperable. I have already devised the plan, and am about to have the chamber constructed, so as to be in readiness for the use of patients during the ensuing winter season at San Remo.

San Remo.

ON THE REMOVAL OF A DEEP SEBACEOUS CYST OF THE NECK THROUGH THE MOUTH, AVOIDING AN EXTERNAL SCAR.

By W. J. WALSHAM, F.R.C.S.,

Assistant-Surgeon to, and Demonstrator of Orthopædic and Practical Surgery at, St. Bartholomew's Hospital; Surgeon to the Metropolitan Free Hospital.

SINCE my attention was called, some ten years ago, to Langenbeck's description of deep sebaceous cysts of the neck (Dermoid or Atheromycysten des Halses), although I have constantly looked for the affection, it has but twice fallen to my lot to see an example of it: once about five years ago at the Metropolitan Free Hospital, where I helped a colleague to remove such a cyst by an incision below the jaw; and once during the last autumn at St. Bartholomew's Hospital, where I removed one through an incision in the mouth. The comparative rarity of deep sebaceous cysts of the neck, and the facility with which I was enabled to remove the whole cyst through the mouth, thus avoiding an external scar, are my reasons for drawing attention to the subject. Sebaceous or atheromatous cysts, says Langenbeck,¹ apart from their frequent occurrence in the scalp and skin, are only found deeply seated in the region of the neck and throat, sometimes under the superficial fascia, sometimes deeper, having attachments to parts of the larynx or pharynx or to the carotid sheath. They appear as tumours of a globular or ovoid shape, with a smooth and even surface, and are tense and elastic to the touch; whilst, with one finger in the mouth and the other pressing upon the swelling in the neck, fluctuation can be distinctly felt through them.

In several of the cases referred to by Langenbeck a transmitted pulsation of the carotid artery was felt on extension of the head; but in these cases the cysts had an intimate connection with the sheath of the great vessels, and most of them were contained in the superior carotid triangle. In both the cases I have seen the growth corresponded with Langenbeck's description, but in neither did I detect any transmitted pulsation from the carotid artery, nor discover any connection

with the carotid sheath, but then they were situated almost entirely in the digastric triangle. Both appeared globular, and to have only superficial attachments; but at the operation for their removal deep ramifications were found extending amongst the muscles of the tongue and hyoid bone. That at the Metropolitan Free Hospital occurred a little below and in front of the angle of the jaw, and extended down the neck to above the level of the hyoid bone. It appeared to be about the size of a Tangerine orange, was freely movable, and fluctuation could be felt through the mouth. On removal deep prolongations were found running in several directions, one as far forward as the symphysis, and others amongst the muscles of the tongue. Notwithstanding these it was fairly easily shelled out with the finger leaving the various structures forming the floor of the digastric triangle exposed to view. The cyst that I myself removed occurred in an unmarried woman thirty-four years old. She had first noticed a swelling under the jaw about five years ago, and it had since been growing gradually larger. She was certain that it had not existed longer than that time. On admission the swelling was about the size of an orange, and situated in the right side of the neck, extending downwards into the neck for about two inches, and upwards into the mouth. It was globular, circumscribed, apparently freely movable, non-adherent to the skin covering it, which was normal, moderately tense, smooth on the surface, and giving no pain when handled. On pressing it upwards from the neck, it could be made to project prominently into the mouth, where it could be felt reaching from the base of the right anterior pillar of the fauces to the symphysis. Fluctuation, with one finger in the mouth and the other on the neck, was readily perceptible. I was unwilling to remove it by an incision in the neck, feeling sure from former experience that notwithstanding that it felt freely movable and circumscribed, it would have deep connections, and therefore that the wound, considering, the laceration and bruising of the tissues which would necessarily ensue, could hardly be expected to heal by the first intention. I was anxious, the patient being a woman, and of not unprepossessing appearance, to avoid a scar. Langenbeck's experience of tapping or incising these cysts, moreover, was not encouraging. In one case treated by incision the cyst filled again and again for four years. Mr. Willett, who kindly saw the case with me, thought that it might be removed through the mouth, and considering the ease with which the former cyst, in spite of its deep attachments, shelled out, I determined to make the attempt. The patient having been brought under the influence of chloroform, a gag placed in the mouth, and the tongue drawn over to the left side, an incision was made in the floor of the mouth from opposite the last molar tooth to the symphysis, and the sublingual gland having been turned to one side, the wall of the cyst was exposed. The capsule was opened, and the cyst separated with the finger quite easily from its posterior, external, and anterior connections. On its inner or deeper aspect the enucleation was less readily accomplished, several prolongations extending among the muscles of the tongue and hyoid bone. In freeing the deeper parts the cyst wall, which up to this time had remained unbroken, was ruptured at its upper part by coming into contact with the teeth. After evacuating the greater part of the contents (pseudo-sebaceous or porridge-like material), carefully preventing any from entering the wound, the whole cyst, with its deep ramifications, was completely removed. There was no hæmorrhage; the wound therefore was not plugged, but only a small piece of oiled lint placed

¹ Archiv für Klinische Chirurgie, Band i., 1860, p. 1.

in it superficially to prevent its closing, and a bandage applied to the neck so as to make gentle pressure upon its deeper parts. With the exception of a sharp rise of temperature on the morning after the operation, which rapidly subsided on removing the lint from the wound, the patient convalesced without a bad symptom. The wound was syringed out hourly with a weak solution of carbolic acid (1 in 100), and gentle pressure continued on the neck by means of a bandage. It completely healed in a fortnight, and the patient was discharged at the end of three weeks without a trace of any external swelling in the neck.

The origin of these cysts would seem involved in some obscurity. In several of the cases quoted by Langenbeck and Gurlt they were attached to the carotid sheath, from or in which they are believed by Langenbeck to grow. In most of the cases the cysts appear to have existed a long time, and in some to have attained a large size. One cyst,* which began below the lower jaw, and at first was no bigger than a hazel nut, in ten years grew so large that it extended to the clavicle. In neither of the cases under present consideration had the cyst any connection with the carotid sheath, nor, as far as I could determine, with either the larynx or hyoid bone. For my own part, I should regard such a connection rather as accidental—i.e., that the sheath of the vessel or other structures had merely become involved in one or more of the out-growing processes of the cyst as the latter increased in size and depth. If such be the case, it is a point in favor of their early removal, for in some of the published cases the cyst has been found so intimately attached to the sheath of the great vessels that its removal has involved the excision of an inch or more of the jugular vein; or, in consequence of its relation to the artery itself, the operation has had to be abandoned. Although no general rule of practice can, of course, be drawn from the experience of a single case, I venture to suggest that where, as here, the cyst is freely movable, and can be made easily to project into the mouth, removal through the mouth will be found the best method of treatment. It may, of course, be objected that such a proceeding involves a deep wound with no depending opening, and that it must be attended with considerable bruising and laceration of the surrounding tissues. I think, however, if pus is prevented from collecting in the deep parts of the wound by maintaining a free opening into the mouth, by frequent syringing, and by applying well-regulated pressure to the neck, that, considering the vascularity of the parts, no difficulty need be apprehended in the rapid healing of the wound. The avoidance of an external scar in the removal of such growths is alone, I think, sufficient to render this method worthy of further consideration.

Weymouth-street, W.

A RAPID METHOD OF DEMONSTRATING THE TUBERCLE BACILLUS WITHOUT THE USE OF NITRIC ACID.

By HENEAGE GIBBS, M.D.,

Curator of the Anatomical Museum, King's College.

THE following method, which I have used for some time with great success, will I think prove useful to those requiring the demonstration of the tubercle bacillus for diagnostic purposes in a rapid manner. The great advantage consists in doing away with the use of nitric acid. The stain is

made as follows: Take of rosanilin hydrochloride two grammes, methyl blue one gramme; rub them up in a glass mortar. Then dissolve anilin oil 3 c.c. in rectified spirit 15 c.c.; add the spirit slowly to the stains until all is dissolved, then slowly add distilled water 15 c.c.; keep in a stoppered bottle. To use the stain: The sputum having been dried on the cover-glass in the usual manner, a few drops of the stain are poured into a test tube and warmed; as soon as steam rises pour into a watch-glass, and place the cover-glass on the stain. Allow it to remain for four or five minutes, then wash in methylated spirit until no more color comes away; drain thoroughly and dry, either in the air or over a spirit lamp. Mount in Canada balsam. The whole process, after the sputum is dried, need not take more than six or seven minutes. This process is also valuable for sections of tissue containing bacilli, as they can be doubly stained without the least trouble. I have not tried to do this against time, but have merely placed the sections in the stain and allowed them to remain for some hours, and then transferred them to methylated spirit, where they have been left as long as the color came out. In this way beautiful specimens have been made, without the shrinking which always occurs in the nitric acid process. The stains may be procured from Messrs. R. & J. Beck, 68 Cornhill, E.C., either in crystals or in solution, ready for use.

THE POISON OF THE VIPER, AND PERMANGANATE OF POTASH.¹

By DR. GIUSEPPE BADALONI,

(Of Nocera-Umbra, Italy),

Corresponding Fellow of the Medical Society of London.

[DR. BADALONI commenced his paper with a short historical sketch of the investigation of the viper poison, from the days of Francesco Redi downwards. Having described the poison apparatus of the viper, he passed on to the chemical nature of the venom, and quoted the analysis of Prince Louis-Lucien Bonaparte, made in 1843, comparing it with Professor Weir Mitchell's analysis of rattlesnake poison, in 1861, as follows:

Viper poison.

Echidnin or viperin, the active principle; a yellow coloring matter; a substance soluble in alcohol; albumen, or mucus; fatty matter; chlorides and phosphates.

Rattlesnake poison.

An albuminoid body, crotafin (the active principle); an albuminoid substance coagulating with heat; a coloring matter, and an undetermined substance, both soluble in alcohol; a trace of fatty matter; chlorides and phosphates.

Echidnin, according to Prince L. L. Bonaparte, had the appearance of a gummy varnish, being inodorous, glistening, and transparent. It detached itself from the watch-glass, when dried, in brilliant scales like those of tannic acid. It was inodorous and without definite taste; it did not redden litmus or turn syrup of violets green; it evolved ammonia when heated with caustic potash; it acted on the blood of animals in the same way as the natural poison; mixed with human blood it darkened its color and arrested coagulation. The mode of action of the poison on the economy was to exercise a depressing influence on the nerve

¹ Naegle: Brünninghausen, Ueb. d. Exstirpat. d. Balgeschwülste am Halse (s. a. 239), s. 51.

¹ Communicated to the Medical Society of London, in an English Translation, on April 16th, by Dr. Isambard Owen.

centres and on the heart. Dr. Albertoni, of Genoa, in 1879, had formulated from his experiments the following results: (1) There was a close relation between the severity of toxic phenomena, the rapidity of the fatal ending, and the blood pressure. (2) When the blood pressure was reduced to about 50 mm., death followed in a few minutes. (3) The blood pressure was always lowered by the action of viper poison. The post-mortem appearances—the multiple hæmorrhagic and inflammatory congestive lesions of the more active and vascular tissues—might be ascribed to the depressed nervous action, or perhaps to the slackening or arrest of the circulation. In 1879 Dr. Jean Baptist de Lacerda, vice-director of the Physiological Laboratory in the National Museum of Rio Janeiro, announced the discovery of organized ferments resembling bacteria in the poison of serpents, and recommended alcohol as an antidote. These organisms Dr. Badaloni had failed to find in viper poison, and on treating the poison with alcohol for twenty-four hours he found its activity in no way diminished. Alcohol, too, had been used by Prince Bonaparte in preparing the echidnin, which possessed all the properties of the viper poison. In 1881 Dr. de Lacerda, abandoning the bacterial view, stated the poison to be a digestive juice analogous to the pancreatic secretion, though far more powerful; and the subcutaneous injection of permanganate of potash in a 1 per cent. solution to be the true and only means of counteracting it. These conclusions, supported by forty experiments, were made public on July 20th, 1881. "The rapidity of the neutralizing action of the substance employed as an antidote," Dr. de Lacerda said, "showed itself not inferior to the rapidity of the disturbing action of the poison." In 1882 the same author published a pamphlet containing a series of clinical cases, to the number of forty, in support of his experimental results. The permanganate, he stated in a circular dated Aug. 1st, 1881, should be injected subcutaneously if the poison had been absorbed by the lymphatics from the connective tissue, and into the superficial veins if it had penetrated directly into the circulation. The requisite indications would be afforded by the relative rapidity and intensity of the general and local symptoms. A bandage should be tied above the wound immediately on the accident, and three or four grammes of the 1 per cent. solution injected, if possible in the track of the puncture, stimulants being given meantime to counteract the general depression. To the action of the poison, as described above, Dr. Badaloni said the permanganate was not a physiological antidote. Its effects, if any, must be due to its chemical action on fermentative substances. Dr. Badaloni then detailed his own experiments with the permanganate, which were as follows:]

First Experiment (Sept. 15th, 1881).—3 P.M.: I took a large and mature *Vipera aspis* just behind the head, and, bringing it against the left side of the upper lip of a large rabbit, made it bite. A few drops of blackish blood oozed from the wound. I made it give a second bite in the middle of the left front paw. After ten minutes I observed the development of toxic phenomena—viz., drowsiness, which quickly passed into somnolence, and slight dilatation of the pupils. A little later a slight degree of meteorismus presented itself, and the head, as if left to itself, fell on one side, as though the animal were oppressed by deep slumber. After fifteen minutes of this pathological condition I made an injection with a Pravaz' syringe of a gramme of the solution, inserting the needle into the areolar plane above the right shoulder, close to the neck. The rabbit seemed little relieved and soon fell into a lethargic state

anew. After the lapse of twenty minutes more I made it walk, but it did not keep its feet and fell. A fresh injection of a gramme. No amelioration; on the contrary, after ten minutes, extreme dilatation of the pupils, followed by convulsions, violent though very short, and death. Although the antidote was not injected in the actual seat of the wound, yet in thirty minutes it should have been able to act on the poison and prevent death. An hour later Dr. Walter Battistini, veterinary surgeon, made the post-mortem examination, from which I quote the following:—Heart dilated, flaccid, free from clots. Blood dark and very fluid, slow to coagulate. Hyperæmia of the mucous membrane of the stomach with a number of submucous hæmorrhagic puncta. Intestines, especially the small, extremely injected, with hæmorrhagic puncta. Mesentery the same. Lungs, liver, spleen, and kidneys normal. With electricity, contraction of all the muscles.

Second Experiment (Sept. 23rd, 1881).—4.16 P.M.: The same viper used on the 15th was applied to the right side of the upper lip of a large and healthy rabbit. Anal temperature 39.7° C. (103° F.).—4.40 P.M.: Bitten by the viper.—4.45 P.M.: Symptoms of poisoning.—4.47 P.M.: Injection of one gramme in the areolar tissue close to the neck. Temperature 39.4°.—5 P.M.: A second injection of a gramme in the same place.—5.37 P.M.: Temperature 38.1°.—6.20 P.M.: Temperature 37.2°.—The rabbit remained for several hours in a state of prostration and apathy, but not of severe depression. After a time it recovered strength progressively, and after twelve hours the temperature regained the normal.

Third Experiment (Sept. 27th, 1881).—2.45 P.M.: A young *Vipera berus* was made to bite the upper lip of the rabbit that had been used in the preceding experiment. Temperature 39.5° C.—2.50 P.M.: Bitten.—2.58 P.M.: Somnolence.—3.35 P.M.: Temperature 38.6°.—4.30 P.M.: Temperature 37.4°.—This time I made no injection at all of the antidote, so as to see if the temperature followed the same curve. In the result the thermometer at 5.28 P.M. marked 36.1°. I left the animal to itself, and when I visited it the next morning it was a little slow in its movements, as in the preceding experiments, but the temperature was restored to the normal.

Fourth Experiment (Nov. 12th, 1881).—2.40 P.M.: The rabbit of the preceding experiment was bitten on the right side of the upper lip and on the left hind leg by two *Viperæ aspidæ*, which had fasted for more than a month. Anal temperature 39.8°.—2.45 P.M.: Bitten by one viper.—2.55 P.M.: Temperature 38.7°; loss of urine; somnolence.—3.10 P.M.: Bitten by the other viper; loss of urine; somnolence.—3.15 P.M.: Temperature 38.7°; loss of urine; somnolence.—3.25 P.M.: Temperature 38.5°.—3.40 P.M.: Symptoms aggravated. Three grammes of the antidote injected into the actual seats of the wounds.—3.45 P.M.: Temperature 37.5°.—Sleep and difficulty of walking more marked. A second injection of the solution of permanganate.—3.50 P.M.: Temperature 37°.—4 P.M.: Dilatation of the pupils.—4.7 P.M.: Temperature 35.6°.—A fresh injection of a gramme. The pupils more widely dilated. Somnolence passing into the comatose state.—4.30 P.M.: Temperature 35.5°.—5.10 P.M.: Temperature 35.2°. Same symptoms.—6.40 P.M.: Temperature 34.5°; insensibility; eye motionless; extreme dilatation of the pupils.—10.15 P.M.: Temperature 35.3°; pupil less dilated and somnolence less; movements easier. The temperature went on rising till, the following morning, though the animal refused food, it had normal agility in its movements.

Recapitulation.—In the first observation two

grammes of the antidote were injected, and the animal died in about an hour. Similarly in the second, where death did not occur, the temperature went continuously down as low as 37.3°C . In the third, without any solution of the permanganate having been injected, the temperature fell to 36.1° , and in the sequel the active power of the poison was weak and unable to produce death. In the fourth, while it is an important point that the notable lowering of the temperature was the effect of the poison of two vipers, five grammes of the antidote were injected without obtaining any benefit. On the contrary, the temperature was reduced to 34.5° an hour and a half after the injection of the last gramme. If permanganate of potash neutralized the action of viper poison, the temperature of the wounded animal, instead of going down, ought after its application, if not to rise, at least to remain stationary; not therefore to fall as far as from 39.8° to 34.5° , or through five degrees and three-tenths. Thus the cases that did not end fatally presented a constant lowering of bodily temperature, which, in spite of the injection of the antidote, continued decreasing until death seemed impending.

I then made another series of experiments on smaller animals—viz., mice (*Mus musculus*) to eliminate the doubt that in the previous experiments death failed to occur by virtue of the antidote, not owing to the enfeebled power of the poison.

1. On Dec. 13th, 1881, at 1.50 p.m., I took a mouse weighing 90 grammes and submitted it to the bite of a *Vipera aspis* on the right hind leg. Immediately I injected two grammes of the solution of permanganate of potash at the same spot. Ten minutes later all the symptoms of poisoning showed themselves severely, and not only did I obtain no amelioration whatever, but the animal succumbed amid convulsions in another thirty-four minutes. The postponement of death for three-quarters of an hour in a little mouse, which in summer falls a victim in from five to seven minutes, at the same time convinced me of the feeble power of the poison when the temperature of the air is cold, and gave confirmation of the inefficacy of the remedy used, all the more as, if four grammes of the antidote sufficed for a man, two should be more than enough for a mouse. Cadaveric rigidity showed itself four hours after death, to disappear thirty-six hours later. The point of injection was in the areolar tissue between the thigh and the abdomen; the liquid had been absorbed and the color of the neighboring tissues was everywhere dark from the injection of the solution of permanganate. But the objection might be raised, was it not the two grammes of the solution of permanganate that, by undue intensity of action, caused the death of the mouse rather than the poison of the viper? On the 17th of the same month I took three other large mice. Before commencing further experiments it was necessary to irritate strongly my vipers, in order to arouse them in some degree from the lethargic state, and I should remark here that the atmospheric temperature had fallen to the freezing point.

2. I caused the first mouse to be bitten on the right leg by a well-grown *Vipera berus*, and at once injected a gramme of the antidote by the actual opening made by the tooth. Symptoms of slight poisoning quickly appeared, but of short duration, and in half an hour the little animal appeared as lively as before.

3. I did the same to the second mouse, with identical result.

4. I placed the third mouse inside a basket, in which I kept four vipers of different sizes and ages. As soon as they saw themselves in company

with a mouse, an animal for which they display the most unbridled hate, they erected their heads and quivered convulsively, emitting prolonged and frequent hisses. Each held its mouth wide open, and waited in readiness for the mouse to move to attack. In fact, after a few movements of the unfortunate stranger, which was endeavoring to flee, all the vipers launched furious blows at it, and their heads fell like hammers on the body of the wretched mouse, which now squealed, now shunned the blows, and now, shrinking and trembling, seemed to seek to calm the anger of its enemies, as if suing for peace. The strife lasted some time, and peace only returned after I removed the poor animal from the cage. It had received no less than eight bites. I did not inject any dose of antidote into this last mouse, which I attentively watched. It kept quieter than the others. Its movements were less agile and more sluggish. It sought neither to flee nor to hide itself, and seemed much prostrated in power. These symptoms lasted for little more than a quarter of an hour, only half the duration of the symptoms in the two preceding experiments, at the end of which time it had returned to its original condition.

From the sum of these experiments of mine three points should remain proved—(a) That the poison of the viper in the cold season exercises an action almost *nil* on even the most delicate organism. In fact, the experiments practiced on days successively colder gave results relative to the level of the atmospheric temperature. (b) That the permanganate of potash is incapable of neutralizing the action of viper poison, since the symptoms, instead of improving after the hypodermic injections, followed all the phases of poisoning. (c) That if death did not actually occur, it was only from lack of power in the poison, and not by virtue of the antidote.

[To these experiments Dr. de Lacerda had objected—(1) That in such small animals absorption of the poison would take place too rapidly for the antidote to reach it in time; (2) that the injection should have been made immediately after the bite, as the permanganate neutralizes the poison only if brought into contact with it before it is absorbed; (3) that Dr. Badaloni had not measured the amount of poison injected. To these objections Dr. Badaloni replied—(1) That, small as the animals were, the effects of the poison were very prolonged, leaving ample time for the action of the antidote. (2) It remained to be shown that the action of a purely chemical antidote would be exercised only in the seat of, and immediately after, inoculation; and, furthermore, immediate injection in the track of the bite was practiced in the case of the mice without any apparent result. (3) The measurement of the poison was unnecessary in experiments of a merely qualitative character. To the experiments of Vincent Richards, cited by Dr. de Lacerda, Dr. Badaloni opposed those of Sir Joseph Fayrer, described in "The Thanatophidia of India," the results of which were purely negative.

Professor Mantegazza had called in question Dr. Badaloni's assumption of the identity of the chemical nature of the viper and rattlesnake poisons, founded on Prince L. L. Bonaparte's analysis, made so far back as 1843. But Professor Weir Mitchell's parallel investigation, on which he relied as well, Dr. Badaloni replied, was made at a much later date (1861) and came to precisely similar results. Prince Bonaparte's work had, further, been cited by Poggiale in 1869 as being in advance of Mitchell's. Considering the purely qualitative nature of these analyses, he considered himself justified in relying upon them, and he believed the two poisons to be in every way identi-

cal, as De Lacerda himself admitted; the greater virulence of the *Crotalus* being due to the amount of poison which it is capable of injecting.

Whatever value should be given to the experiments made with permanganate of potash by different observers up to the present date, the question of an antidote to viper poison remained unsolved, for this substance had not yet answered the expectations of European experimenters as it had in the hands of Dr. de Lacerda.]

OF

HOSPITAL PRACTICE

BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendi via, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Proœmium.

MIDDLESEX HOSPITAL.

ACUTE TETANUS, FOLLOWING A CONTUSED WOUND OF THE FLESHY PART OF THE END OF THE THUMB; DEATH.

(Under the care of Mr. GEORGE LAWSON.)

For the notes of this case we are indebted to Mr. Guilding.

The following case is an example of acute traumatic tetanus, a disease from which a patient very rarely, if ever, recovers. On Monday, January 22nd, the man met with a comparatively slight injury to the thumb. On Thursday the premonitory symptoms of tetanus commenced in a feeling of slight stiffness at the back of the neck. On Friday there was an extension of these symptoms, and on Saturday afternoon feeling himself worse the patient applied to the hospital and was admitted. When admitted he had had no convulsive attacks. The convulsions did not begin until eight o'clock in the evening, and the patient died in one of them at about ten o'clock the following morning. The treatment consisted in the subcutaneous injection of the extract of Calabar bean, repeated injections of morphia, and the putting the patient under chloroform. The thumb was amputated with the faint hope that the removal of the source of irritation might exercise a favorable influence in quieting or arresting the convulsions. Unfortunately the medicines exercised no power in controlling the progress of the disease; they certainly eased the suffering of the patient, but the tetanic convulsions increased in severity, and in fourteen hours from the first convulsion the patient died. The following are the details of the case.

Eli L—, aged fifty-one, a strong muscular man, with dark complexion and iron grey hair, was admitted into Broderip ward on Jan. 27th, 1883, with tetanic symptoms following an injury to the right thumb. On Monday, Jan. 22nd, five days previously, the patient crushed his finger, and at the same time tore the skin over the centre of the pulpy tissue which covers the last phalanx of the thumb for about a quarter of an inch in extent. From this time the finger was very painful; it inflamed and suppurated. On Thursday afternoon the patient felt a slight stiffness at the back of the neck. On Friday he found that his neck was very hard and rigid, and that his head was drawn forcibly back; he also noticed that he could not open his mouth as wide as usual. On Saturday, Jan.

27th, feeling himself worse, he came to the hospital in the afternoon, and was at once admitted.

State on admission: The patient spoke very indistinctly, owing to his utter inability to separate his lower from his upper jaw, and on applying force to them it was impossible to part them. He complained of pain at the epigastrium, and down the back. On lifting the patient up in bed the head was pulled violently back on to the shoulders, as if by a steel spring, and the muscles at the back of the neck could be felt tense and rigid. There was no rigidity or spasm of any of the other parts of the body. The patient lay in an apparently drowsy state, but could be easily aroused, and answered all questions readily. The bowels were constipated, not having been opened for five days. Temperature 97°. On examining the thumb the tissues over the first and second phalanges were inflamed and swollen, and from a small wound about a quarter of an inch in length over the palmar surface of the last phalanx there was a slight discharge of pus. Any attempt to swallow increased the spasms to such an extent that it was impossible to give him either medicine or food by the mouth. About 8 p.m. the patient began to have severe convulsive attacks, which were greatly aggravated by the least attempt to touch him. The body was violently contracted into a condition of opisthotonos, the legs were rigid, and the muscles of the back like rods of iron. The intercostals, and probably the diaphragm, were in a state of strong spasm, as respiration during the attacks was arrested, and the face and surface became of a dark-bluish color. The flexors of the forearm were free from spasm. These attacks came on about every half-hour, some being more severe than others. At about 11 p.m. he had a most severe attack; his muscles of respiration were involved; he ceased to breathe, his heart and pulse stopped, and the patient was black in the face, when, with a sudden bound, the pulse began again, and he recovered for the time. In this attack his tongue was caught between his teeth, and almost bitten in two. Mr. Lawson then saw the patient, and amputated the thumb after he was put under the influence of chloroform. The patient inhaled nearly four ounces of chloroform before he was well under its influence, and even then his limbs were rigid. Before awaking from the chloroform the patient was injected subcutaneously with half a grain of the acetate of morphia. Under the combined effect of the chloroform and the morphia the patient was quiet for nearly three hours. At a quarter to three o'clock the convulsions recurred. The first convulsion was at about a quarter to three o'clock; the second at half-past three; the third at a quarter-past four; the fourth at about a quarter to five. From this time the convulsions were repeated every ten or fifteen minutes, and he died in one of them at ten minutes to ten on Sunday morning.

The treatment during the short time the patient was in the hospital was as follows: Soon after admission he was injected subcutaneously with the one-sixteenth of a grain of the extract of Calabar bean, and this was repeated in about one hour. Finding no relief, a third of a grain of the acetate of morphia was injected subcutaneously. The injured thumb was then amputated, and whilst the patient was under the influence of chloroform he was injected with half a grain of the acetate of morphia.

Necropsy (abstract from the notes of post-mortem examination made by Dr. Fowler).—Thorax: Organs healthy; some post-mortem congestion. Kidneys were enlarged, congested, and indurated; capsule adherent; on stripping off the capsule a granular surface was left, but no wasting of cortex.

Brain: Vessels (veins) of meninges over occipital region were full of blood (post mortem). On removing the membranes no marked changes were seen in the pia mater or convolutions. On sections being made through the brain, no decided changes could be detected with the naked eye. There were some post-mortem coagula in the lateral sinuses. The base was unchanged. Cord: Membranes showed some post-mortem congestions, otherwise they were healthy. There was an enormous number of calcareous patches in the membranes, extending from above the cervical to below the lumbar enlargement; but beyond this nothing abnormal was detected.

ROYAL ARSENAL HOSPITAL, WOOLWICH.

CASE OF TRAUMATIC GANGRENE OF THE PENIS AND SCROTUM; NECROPSY.

(Under the care of Surgeon-Major W. F. STEVENSON.)

W. J —, a painter, married, aged forty-three, was admitted into hospital on Jan. 3rd, 1883, with great swelling and ecchymosis of the penis and scrotum, but not extending into the perineum. He stated that on the previous day he had strained himself while at work by attempting to support a tent-pole (weighing thirty pounds) which was falling on him, but that he did not fall and did not receive any blow or direct violence of any kind. He suffered considerable pain at first, but remained at work during the afternoon. When he went home he applied fomentations.

On admission, at 10.30 A.M., the scrotum was as large as an infant's head from effusion of serum into the cellular tissue, and the penis much enlarged from the same cause; these parts were also almost black from ecchymosis. The perineum was not affected. There was not much pain. On the left side of the penis the cuticle had been removed from a piece of skin about the size of a half-crown, and a thin grey slough remained. The man looked very ill; he was pale and cold; the pulse weak and 136; he had voided water freely during the night, and stated that it contained blood. A catheter (No. 10) was passed with ease, and a small quantity of urine containing no blood was drawn off. During the day he passed a very little clear urine without the use of the catheter. In the evening he was still further collapsed; the skin was cold and moist, and the pulse imperceptible. During the night he was very restless, and next morning his condition, both locally and constitutionally, was much worse; the swelling had passed into the perineum, and that of the penis and scrotum had increased. Gangrene of the parts first affected had evidently taken place. A very little, if any, urine had been passed during the night. An erysipelatous redness was extending over the pubes and abdomen. Tongue was furred and dry; surface cold and clammy; no pulse. A catheter was passed, but no urine was found in the bladder. Several incisions were made into each side of the penis, scrotum, and perineum, giving exit to a large quantity of serum. Two incisions were also made into the abdominal wall where the erysipelas appeared, but the circulation was so feeble that blood hardly flowed from them. In the evening the swelling was much less in consequence of the continuous drain of serum which had taken place from the incisions. There was no urine in the bladder. The state of collapse was profound, and the man was delirious and very restless. This condition lasted until 1 A.M., when he died exhausted. The treatment had consisted in efforts, by means of warmth and stimulants, to combat the state of collapse which was well-marked even on admission, but

which, notwithstanding all endeavors to the contrary, increased up to the time of his death, about fifty hours after the strain was supposed to have occurred. Opium was given internally and fomentations used locally.

On post-mortem examination, the internal organs were found healthy; there were some old pleuritic adhesions in the right side of the chest. The bladder was healthy and quite empty; the urethra was healthy in appearance, except towards the outer end, where, for about one inch, there was some ecchymosis. The cellular tissue of the penis and scrotum was infiltrated with serum; the body of the penis was distended with dark blood, which oozed out on section of the corpora cavernosa; the tunica vaginalis contained very little fluid. That such a condition should have originated in a strain, such as described, would seem strange. A witness at the inquest which took place stated that the tent-pole fell between the man's legs. If this occurred, which the man himself denied, possibly the penis received a contusion at the situation of the ecchymosis found in the urethra, causing rupture of some of the vessels in the corpora cavernosa, resulting in such distension of those organs as to interfere to such an extent with their circulation as to bring on gangrene of the penis, which spread backwards to the neighboring parts.

MANCHESTER ROYAL INFIRMARY.

CASE OF POPLITEAL ANEURISM; RUPTURE INTO KNEE-JOINT; AMPUTATION THROUGH THE THIGH; RECOVERY.

(Under the care of Mr. WHITEHEAD.)

For the following notes we are indebted to Mr. G. Preston.

William B —, aged forty, a laborer, was admitted on January 1st, 1883, suffering from aneurism of the left popliteal artery. His previous history was as follows: About seven months ago the patient's left leg was crushed just below the knee. The joint, he says, was severely strained by the accident, but it was not so badly hurt as to keep him from his work. On the following morning he noticed a small lump, about the size of a marble, at the lower part of the popliteal space. He suffered no pain in it; but still he considered it advisable to stay at home that day and rest his leg. On the next day, the second after the accident, he went to his work as usual, and for fourteen days he noticed nothing further as regards the lump, but at the end of this term he experienced some slight pain when walking or when he tried to extend his leg fully. On examining the swelling he found that it had increased to the size of a hen's egg. Though the patient still went on with his work, the condition of his leg remained the same up to a week before his admission, when he sustained what he describes as another strain of the same knee; by the following day the swelling had increased considerably in size, and he suffered great pain in the knee and down the leg. He stayed in bed and applied hot fomentations and poultices to the swelling, the result being a gradual increase in the size of the swelling and an increase in the pain. He now, for the first time, consulted a medical man, who sent him to the hospital.

On admission the left knee was much swollen, the outline of the pouches of the synovial membrane being particularly well marked out, but there was no pulsation of them, and the patient stated that he had never noticed any pulsation in front of the knee; behind the knee, in the popliteal space, and to all appearances almost filling it, was a fusiform swelling, which was distinctly

pulsatile and expansile; very slight pressure on the femoral artery completely stopped the pulsation; the pulse could not be felt in the tibial arteries, and the left leg was much colder than the right, but there was no oedema of the leg; a very loud systolic bruit could be heard over the tumour, and also over the femoral artery. The patient had severe pain in the knee-joint and down the leg to the toes. He had aortic stenosis and regurgitation, and a hypertrophied left ventricle. He had a well marked "water-hammer" pulse. The patient was put to bed, and a Signoroni's tourniquet applied to the femoral artery at once; the flow of blood was not stopped entirely, though nearly so. The tourniquet was kept applied for about two hours at a time (the patient could not bear it longer) during that day and the following, but on the third day after admission his leg became extremely painful, and he took the tourniquet off. It was now found, on examination, that the knee was more swollen and tense, and that there was distinct pulsation above and below the patella in the situation of the distended pouches of the synovial membrane of the joint. The tourniquet was again applied so as to completely control the blood-supply to the limb; the tourniquet was slackened on Mr. Whitehead's arrival, but now the pulsation in the knee had ceased. That the aneurism had ruptured into the knee-joint was made certain by drawing off blood from the joint with a small syringe. Owing to the man being the subject of aortic disease, with consequent strong pulsation in his arteries, together with the fact that the vessels appeared to be atheromatous, it was thought advisable to abandon the ligature in this case, and resort to amputation at the junction of the middle and lower thirds of the thigh.

Pathological examination.—It was found that there was a large fusiform aneurism of the popliteal artery; the knee-joint was distended with blood, and on removing this, it was found that there was a small circular aperture in the posterior ligament of the joint, which communicated with the sac of the aneurism. The surrounding structures were perfectly free from any extravasated blood.

After the operation the tourniquet was kept in position for fourteen days, moderating, to a slight extent, the flow of blood to, or rather the strength of the arterial pulsation in, the stump, as secondary hæmorrhage was considered very likely to occur. No such catastrophe happened, however, and now the stump is quite healed, and the patient convalescent.

GUY'S HOSPITAL.

RECTO-VAGINAL FISTULA; COLOTOMY; DEATH.

(Under the care of Mr. BRYANT.)

For the report of the following case we are indebted to Mr. Tresidder:

S. E. S—, aged forty, was admitted into Lydia ward on April 20th, 1881. She was in the hospital three years previously, suffering from what was considered to be syphilitic stricture of the rectum. She was treated with bougies and sponge-tents, and when discharged was much relieved. From that time there had been a constant discharge from the rectum, and occasionally a little blood. There had also been much pain across the stomach, and her motions had always been loose. For about a year before admission she had noticed fæces come from the vagina, and for six months nearly the whole had so passed.

On admission, the rectum was apparently closed up, scarcely admitting the tip of the little finger. There was a fistula opening from the rectum to the

vagina, and another from the vagina perforating the perineum. She had been subjected to much ill-treatment, and was but poorly nourished.

On May 3rd, under the anæsthetic mixture (alcohol, chloroform, and ether), she was turned upon her right side, and a pillow placed under her loins. An oblique incision, four inches long, was made just above and parallel to the crest of the ilium. There was not much fat, and the outer border of the quadratus lumborum muscle was easily found. Below this the kidney was felt and pushed aside, and the colon was hooked by means of the finger. The colon was then transfixed by two sutures, opened, and the edges secured. No fæces passed, and the patient was not sick after the operation.—4th: Ordered a one-grain opium pill every six hours; pulse very quick and feeble; respiration 48; complained of headache.—6th: At the posterior corner the bowel had not united to the surface, and there was a discharge of inflammatory material. 23rd: The rectum was washed out, and was open throughout the whole extent. No fæces were removed, and only a little mucus. The vagina also was washed.—29th: The patient had very rapidly become emaciated, and now looked bluish and pale, and lay inclined to the right side, and took short respirations. Over the front of the right lung were sharp inspiratory and expiratory râles of a tubular character. The bases were not examined.

June 3rd.—Vaseline used in dressing the wound; it was covered with a piece of protective.—9th: On removing the dressings they were found to be blood-stained, and when the wound was syringed a large quantity of disintegrated blood-clot came away.—13th: The wound looked more healthy, and had improved since the vaseline had been used. There were two red spots which had appeared over the right trochanter.—15th: In great pain from sores on her back.—16th: Died.

Necropsy.—The wound of the operation was almost healed, but a large abscess was found behind the descending colon. The rectum, sigmoid flexure, and descending colon bore traces of ulceration. There was great thickening of the coats of the rectum, forming a stricture.

STRICTURE OF RECTUM; OBSTRUCTION; COLOTOMY;
WELL.

(Under the care of Mr. BRYANT.)

For the following notes we are indebted to Mr. Tireman:

Charles C—, aged sixty-four, was admitted on June 16th, 1881, into Job ward. There was no history of syphilis. Since the previous Christmas the patient had had diarrhoea with great pain over the right hypochondrium and lower part of the abdomen. During the whole of this time he had passed no solid motion. He had sometimes gone to stool as often as sixteen times in the day, but nothing had passed except slime and blood. His abdomen had been distended more than once, but was on admission larger than ever. On Monday, for the first time since the onset of his symptoms, he passed a tolerably solid stool, and since then he has not been to stool. He has taken no food except a little milk and tea. On Tuesday and the whole of the following day he vomited continually; the vomit was brown and offensive to the taste and smell. On the day before admission he passed a little flatus and a little slimy motion.

On admission he was much emaciated. His face and hands were of a dusky-red color. His hands and feet were cold and bluish. The tongue was dry and covered with white fur. The abdomen was moderately hard, the distension being as great in the lateral parts as in the centre. There was no

pain on handling. The coils of the intestines could be seen and felt, but there was no visible peristalsis, even after lightly rubbing the surface, but the patient said he had seen a creeping movement. No gurgling could be heard. The patient was troubled with hiccough and passed a good deal of flatus, especially when speaking. Mr. Bryant passed his finger into the rectum and found a stricture "very much resembling an os uteri."

Operation.—On June 18th, under chloroform, a transverse incision four inches long was made midway between the last rib and the iliac crest. The vessels were twisted; the fascia and fat were drawn aside, and the bowel when exposed was secured to the edges of the wound by two silk sutures. The gut was opened, and each of the sutures divided in the middle, and the four corners of the gut were tied back. The wound was dressed with terebene lint and a binder applied. One vessel in the wall of the gut was ligatured. Opium suppository.—20th: Passed a good night, and feels quite comfortable; is taking milk. Temperature 100° 2'. Opium pill, one grain three times a day. The posterior sutures seem to have slipped, and there is a good deal of fecal matter about the wound. There was an enormous discharge of feces after the operation, and the abdomen has gone down to the natural size.—23rd: Looks very much better; he has lost the dusky hue of face, and coldness and blueness of the extremities. The tongue is now quite clean and healthy. Is taking milk and arrowroot and beef-tea. Temperature and pulse normal, and the patient is free from all pain. The remaining stitches were removed.—27th: Complains of great pain in the left side. Appetite continues good; the wound looks healthy. Temperature 99°.

July 13th: Temperature normal. There is prolapse of the bowel, but the wound looks well, and the patient is otherwise better.—26th: Daily passes motions per rectum. The colotomy wound nearly healed.

Aug. 13th: Allowed to put his clothes on and walk about.

Sept. 5th: Urine examined; large quantity of urates, no albumen. Colotomy belt supplied.—7th: Discharged. The patient has a perfectly artificial anus, and, with the exception of a slight pain across the lower part of his back, is quite comfortable. His general health is good. He relieves his bowels twice a day, and has no inconvenience from the feces escaping.

CASHEL UNION HOSPITAL.

UNUSUAL TERMINATION OF MORBUS COXÆ; DELIRIUM; CONVULSIONS; AMAUROSIS; DEATH.

(Under the care of Dr. LAFFAN).

M. D.—, aged fifteen, a scrofulous young laborer, was admitted March 14th, 1881, for morbus coxæ in left side. The disease was in the first stage. He was put up in Sayre's long-extension splint (figured in page 269 of Dr. Sayre's work on "Orthopedic Surgery"). This splint, though applied with the greatest care, could not always be borne, and it had to be now and again removed. When the boy was confined to bed he scarcely ever complained of it, and the relief it afforded to the pain was very marked. Though at first, and for some weeks, the same immunity from pain was enjoyed when taking exercise, which he was freely allowed to do in the hospital grounds, yet afterwards the apparatus had to be removed from time to time and the patient allowed to rest in bed. Cod-liver oil and syrup of the phosphate of iron were given internally, and counter-irritation was locally applied. On this treatment he progressed

fairly for some months, but an abscess formed on the front of the thigh which appeared to be connected with the joint; and from this there was a perceptible declension in his condition. Diarrhœa was the most prominent intercurrent symptom, and for this no obvious exciting cause could be assigned.

From the end of August meat had to be stopped on account of diarrhœa.

By Sept. 1st his appetite had almost entirely disappeared. From the 1st to the 3rd he scarcely took anything; on the 4th a violent frontal headache set in, which continued for a whole fortnight, with nocturnal remissions. On the 12th, 13th, 14th, and 15th he was seized with uncontrollable vomiting. On the 17th delirium, with occasional convulsions, set in, and these continued at intervals for about three days, during all of which time he was entirely unconscious. At the termination of the convulsions he was found to be completely amaurotic. On one of those days he vomited a large worm.

From this time forward till the date of his death (Oct. 5th) the vital powers rapidly failed. There was occasional severe vomiting, with delirium and severe convulsions from time to time. On Sept. 26th it was noted that he picked his nose so violently that his hands had to be tied. Floccitation and involuntary evacuations preceded the final scene for some days. Delirium and convulsions were present from time to time, and unconsciousness, which from its first invasion had at intervals been present, became profound and permanent, and closed the final death scene.

Remarks.—The treatment pursued in this case did not realize the benefits predicted for it by Dr. Sayre; but, on the other hand, no connection could be traced between it and the strange cerebral symptoms which carried off the patient. Were it not for a case reported by Dr. Graves in his clinical lectures, and for a few similar ones recorded since then in which cerebral symptoms just as marked as those in my case were present without any cerebral mischief whatever, and where abdominal lesions only were demonstrated after death, it would be deemed absurd for anyone to question the presence of cerebral disease in the foregoing case. Unfortunately no post-mortem examination was obtainable, and I can only therefore indulge a speculation as to whether intestinal worms might not have been responsible for all the head symptoms. Suitable vermifuge treatment was, of course, tried and persisted in from the moment of the first discovery of the worm; but this was barren of result so far as the expulsion of any others was concerned. The case is of some little interest on account of the unusual termination of hip disease it presents, and of the important question of the simulation of profound centric lesions by peripheral irritation, which it at least will recall to the mind of the thoughtful reader.

OBSCURE THORACIC TUMOUR.

(Under the care of Dr. LAFFAN.)

The following case possesses the interest which always attaches to those in which certainty of diagnosis is impossible. Positive signs of tumour were absent, but the intermitting dysphagia, pupillary contraction, and inequality of radial pulse, afforded a reasonable presumption of the presence of an intra-thoracic growth. Whether this, however, was cancerous or aneurismal the existing signs and symptoms did not afford means for discriminating. There were present and absent those that pointed both ways; while the last fatal hæmorrhage pointed more towards aneurism, the absence of the peculiar cough, cardiac murmur, etc., told the other way. A post-mortem examination

would have solved the difficulty; but the law must deal more liberally with Poor-law hospital physicians if these are to be available when the interests of humanity and science demand. This fact Dr. Laffan has in vain brought under the notice of the Collective Investigation Committee.

N. W—, laborer, aged sixty-four, was admitted on Feb. 8th, 1882. He had for five weeks before admission, felt the food and drink stop in the passage, and had to be immediately ejected. At other times both food and drink passed down. The first time he noticed the difficulty was on the occasion of taking a pint of porter. During the five weeks previously referred to, when the food and drink did sometimes pass, it was with some difficulty. He was of intemperate habits, and lived, of course, poorly. He had not sustained any injury, and had not had syphilis.

Present state.—March 24th: His general appearance is somewhat wasted, particularly about the face. He sleeps well. He complained of a lightness in his head for the past ten days. His sight is weak; the right pupil is larger than the left. The tongue is somewhat coated and full of transverse indentations. The left pulse is much fuller than the right. Some râles in chest; he coughs a little and expectorates; some slight bronchitis exists; heart sounds normal. The appetite is becoming poorer; he spat up this morning about a wineglassful of blood. On four or five occasions he spat up a trifling quantity; bowels very costive, and not moved without medicine. Urine, specific gravity 1020; no albumen. Soon after his admission a probang was tried, but failed to pass the entire way, and when drawn up was found covered with blood and pus. For the last few days he suffered considerable pain in the epigastrium, between the two scapulae and in the right shoulder. No other signs could be detected.

Further history.—The respiration continued high; the troublesome cough persisted; lightness in the head and weakness of sight occasionally assailed him; the appetite gradually decreased. There was occasional hæmoptysis, sometimes a large and at other times a small quantity of blood being spat up. Pus was spat up on more than one occasion mixed with the blood. He continued to suffer from dysphagia, but inconstantly, as at times the food passed readily. Decubitus was on more than one occasion rendered impossible by the severity of pain between the shoulders. He complained of great coldness in the feet. On April 15th he spat up a great quantity of pus; on that day, and for two days previously, he suffered from a most harassing cough. During the night of the 15th he spat up five or six times a small quantity of pure blood; on the 16th he suddenly spat up a large quantity of blood and died immediately.

Remarks.—The treatment in this case was directed to meet symptoms, and any detailed account thereof would convey no information. From first to last bronchitic emphysematous signs alone were detected. There was nothing detected by auscultation or percussion which could clearly point to the existence of cavity or tumour, and the exact diagnosis therefore must remain in doubt.

STANLEY HOSPITAL, LIVERPOOL.

FRACTURE OF HUMERUS, WITH DISLOCATION AT RIGHT SHOULDER AND ELBOW.

(Under the care of Mr. ROBERT JONES.)

R. P— whilst plastering a lofty ceiling fell, and in falling grasped at an open door. He came next day to the Stanley Hospital suffering from dislocation of the right shoulder and elbow with

(4)

fracture through the middle of the right humerus. The head of the humerus was felt beneath the clavicle. The radius and ulna were dislocated backwards, and the fracture was oblique. Splints were temporarily adjusted in order to permit of the necessary manipulations for reducing the luxations. This was easily completed without the administration of ether, the splints were readjusted, the arm placed in a sling, and the man requested to attend as an out-patient. In six weeks from the date of injury consolidation had taken place, and movement both at elbow and shoulder was free and painless.

In treating the case it was thought wise to fix the elbow so as to restrain all movement, as signs of effusion appeared on the third day. This, however, was rapidly absorbed. The reductions were easily accomplished by gentle manipulations. The patient had at previous times dislocated both hips, and on three occasions the left shoulder.

LONDON HOSPITAL.

DISLOCATION OF THE HIP-JOINT BACKWARDS; REDUCTION BY MANIPULATION; REMARKS.

(Under the care of Mr. RIVINGTON.)

GEORGE W—, aged twelve, was admitted on March 23rd, 1883. He had been running, and suddenly slipped and fell, his left leg shooting forwards and outwards. He felt something give way at his left hip-joint, and was in great pain for a few minutes. He was unable to rise or walk, and was brought to the hospital in a cab.

On examination, the left leg was found to be one and a half to two inches shorter than the other. It was adducted, flexed, and rotated inwards, the lower part of the left femur passing over the lower third of the right femur, and the toes resting on his right instep. There was very little mobility; the trochanter was elevated, and the head of the bone could be felt some little distance behind the acetabulum and below the dorsum ilii. Mr. Rivington was sent for, and the lad was placed under an anæsthetic. The senior dresser was asked to reduce the displacement. The thigh was flexed on the abdomen, adducted, and brought down without effect on the displacement. It was then flexed, slightly abducted, rotated outwards, and extended, care being taken not to carry these movements too far, when the head of the bone at once slipped into the acetabulum, with an audible snap. A splint was applied to prevent the reproduction of the dislocation, and was retained for a fortnight. He was kept in bed for a week or two longer, then allowed to get up and was soon discharged cured.

Remarks by Mr. RIVINGTON.—This case illustrates the great facility with which dislocations of the hip are produced when the leg is abducted. Mr. Morris has shown that the direction which the head of the bone will take after escaping from the rent in the lower part of the capsule depends upon what may be termed the secondary postures. If the thigh is flexed and rotated inwards, a backward displacement will result; if extended and rotated outwards, a forward displacement is produced; and if extended without rotation, the displacement will be in the downward direction. What was the exact disposition in the present case was not clear from the description of the patient. It is probable that Mr. Morris's views in regard to the production of dislocations at the hip during abduction will receive strong support from cases occurring at an early period of life. One case of dorsal dislocation in a lad of seven, whose foot slipped backwards and outwards in walking, he has recorded in his paper in Vol. IX. of the *Medico-*

Chirurgical Transactions; and I find an instance of thyroid displacement related by Mr. Russell in the *British Medical Journal* for Nov. 2nd, 1878, as occurring to a lad of fourteen. The youth, W. B—, was playing at football and jumped on the back of a playfellow, when they both came to the ground. W. B— alighted on his feet, but they slid asunder, and the dislocation downwards was produced. The case further shows the ease with which properly directed manipulation will reduce an ordinary dislocation in which the capsule is freely torn below. The great point to attend to in reducing sciatic and thyroid displacements is not to carry the manipulations too far in any direction, as these forms of dislocation are readily convertible into each other. Bigelow recommends the conversion of the obturator into the dorsal displacement, which is easy of reduction. This conversion occurred in Mr. Russell's case involuntarily, and in a case of my own, reported in *THE LANCET*, in 1878, when I was trying to avoid it. The dorsal displacement is much less likely to be transformed into an obturator displacement than the obturator into the dorsal; and I have not seen it occur in any of the cases which have come under my observation.

GLASGOW ROYAL INFIRMARY.

THREE CASES OF DISEASE OF THE STOMACH AND INTESTINES.

(Under the care of Dr. MATTHEW CHARTERIS.)

We are indebted to Dr. James McNish for the following notes:

CASE 1.—John McN—, aged forty-two, a laborer, was admitted on October 2nd, 1882, complaining of pain, with tenderness on pressure, in the epigastrium, and vomiting. The pain was most severe at a point about two inches to the right and one and a half above the umbilicus. The symptoms first appeared three months before admission, and had gradually increased in severity. At first they were those of simple indigestion, heartburn, etc.

On admission the patient was pale and emaciated, but not distinctly cachectic, and his countenance bore an anxious and pinched expression, indicative of abdominal trouble. No tumour or induration could be made out, but there was very considerable tenderness on pressure over the area mentioned above. He vomited frequently after food, and this seemed to some extent to alleviate the pain. The vomited matter consisted of a brownish sour fluid, which the patient said had a very disagreeable taste. The bowels were constipated, never acting without the aid of purgatives or enemata; the appetite was bad; the tongue coated with a thick white fur on the dorsum, but red and glazed at the tip and edges, showing also signs of indentation by the teeth. On exertion the patient suffered considerably from dyspnoea, but on examination the lungs and heart were found to be healthy. On October 10th and 11th he had severe attacks of hæmatemesis, which weakened him a good deal. From this date he gradually sank, and died on October 22nd. The treatment consisted of the use of aperients and enemata to overcome the obstinate constipation, sedatives internally and externally to relieve the pain, and the subcutaneous use of ergotine to arrest the hæmorrhage.

Necropsy, forty-four hours after death.—The smaller curvature of the stomach was found to be firmly adherent to the under surface of the liver; the latter organ being firmly united to the diaphragm, so that it was with difficulty separated from it. At

the point where the stomach was most adherent to the under surface of the liver—viz., immediately to the left of the longitudinal fissure—there was a transverse constriction of the former organ, not sufficient, however, to divide it into two distinct parts. The pyloric end of the stomach was greatly distended, and the cardiac orifice of the œsophagus was approximated to the pylorus, as a result of contraction of the lesser curvature. The explanation of the approximation was that there was a large deep ulcer on the smaller curvature corresponding to the point at which the outer wall of the stomach was adherent to the liver. Close to the left edge of the ulcer there were two small openings, which on examination were found to be the open ends of bloodvessels. The floor of the ulcer was covered with small, soft, elevated nodules, which, on being examined with the microscope, were found to be purely inflammatory in nature, without a trace of malignant disease, being composed of cicatricial tissue and without evidence of recent ulceration.

CASE 2.—Duncan C—, aged forty-three, a brassfounder, was admitted on Dec. 8th, 1882, suffering from obstinate constipation, pain, and tenderness in the epigastric region, with loss of flesh and extreme weakness. According to the statement of the patient (who, it may be mentioned, took large quantities of alcohol, and had done so for years) he had suffered for a considerable time from dyspeptic symptoms, although not severely, and twelve months before admission he commenced to vomit about an hour and a half after food, more especially if he had taken a hearty meal. This occurred almost daily for a time, but latterly he had been able to retain his food for two or three days without vomiting. The food, he said, never seemed to leave the stomach, but accumulated, causing considerable inconvenience from distension and flatulence; and at the end of two or three days he would vomit a large quantity of a dark-brown fluid, which vomiting was followed by relief of the pain. The vomited matter, upon examination, was found to contain sarcinae and torulae in abundance. His previous history as regards health was good, and the only point in the family history which would be of importance in the case was the fact that a sister had died of cancer of the womb.

On admission the patient was found to be weak and emaciated, with a haggard and anxious expression. The abdomen appeared retracted in the hypochondriac and epigastric regions, but below these it was distended and highly tympanitic. On palpation gurgling was felt all over the abdomen, with great tenderness in the epigastric region, more marked at a point midway between the umbilicus and ensiform cartilage. No tumour or induration could, however, be made out. The patient gradually sank and died, after having suffered great agony, on Jan. 16th, 1883.

The treatment consisted of nutritive enemata, eight ounces of beef-tea being exhibited three times daily. To neutralize the acid eructations and prevent fermentative changes in the stomach the hyposulphite of soda was given in fifteen-grain doses thrice daily. To allay the pain, hypodermic injections of morphia were given. During the last fortnight he took a little sago by the mouth, which caused vomiting upon one occasion only.

Necropsy, twenty-four hours after death.—The stomach and intestines were found matted together with recent lymph. The walls of the stomach were greatly thickened, and the organ itself was much distended. At the pylorus, and extending backwards for about an inch and a half, there was a large irregularly shaped ulcer, bridged over at one part by a band of mucous membrane about a

quarter of an inch broad. Close to the valve there was great thickening of the walls of the stomach, so that the orifice was almost closed. On microscopic examination of a section, taken from a tumour at the orifice of the pylorus so as to include a portion of the duodenum, there were found evidences of recent inflammation. The tumour seemed to be composed almost entirely of muscular tissue, the fascioli of which were separated by collections of round cells in some parts, and in others by cells closely resembling those met with in myxomata. The inner surface of the tumour was lined by an irregular layer of tissue formed of spindle cells and large stellate cells embedded in a very abundant homogeneous matrix. This tissue seemed to have replaced the mucous membrane, as only at one or two points was there any evidence of an epithelial layer, and it is a point worthy of note, that in the tumour itself, even at its thickest part, where it measured fifteen millimetres, there was no trace of epithelial cells.

CASE 3.—Wm. B., aged forty-seven, a tailor, was admitted on Oct. 14th, 1882, complaining of pain in the whole abdomen, more severe, however, in the left iliac and supra-iliac regions. The commencement of his illness dated twelve months back, when he became constipated, dyspeptic, and experienced pain in the abdomen. These symptoms gradually increased in severity.

On admission he was found to be emaciated and anæmic, with poor appetite, constipated bowels, and a constant gnawing pain in the abdomen, increased to some extent on pressure and movement. The abdomen latterly became markedly distended and tympanitic. During the last five weeks of his life the patient vomited frequently, the vomited matter being of the nature of coffee grounds, but without sarcine and torulae. He only took small quantities of milk and beef-tea. To allay the sickness iced lemonade was given. During the last three weeks of the illness he had no passage from the bowels except of flatus. To relieve the obstinate constipation, castor oil, croton oil, and two turpentine enemata were used in succession, but without effect. A remarkable circumstance in the case is that for the last fortnight the patient was free from pain.

Death took place on Nov. 4th, 1882.

Necropsy, sixty-one hours after death.—At the upper part of the sigmoid flexure the bowel was found to be completely occluded by a large cancerous mass, which protruded into the neighboring part of the bowel. On opening the bowel a fungating mass was found about the size of a small orange. The growth itself was narrower at the base than at the parts beyond, so that the part of the tumour away from the bowel overlapped the adherent portion. The bowel below the tumour was contracted, while that above it was distended. The liver weighed fifty-eight ounces, and was studded with secondary cancerous nodules. On a microscopic examination of the tumour being made, it was found to present the characters of soft cancer. The stroma was very small in amount, while the epithelial cells were unusually abundant.

ST. VINCENT'S HOSPITAL, DUBLIN.

TWO CASES OF ACUTE RHEUMATISM RAPIDLY CURED BY LARGE AND FREQUENTLY REPEATED DOSES OF SALICIN.

(Under the care of Dr. QUINLAN.)

For the report of the following cases we are indebted to Mr. Kenna, resident surgeon.

CASE 1.—Joseph G., aged twenty-three, single, a grocer's assistant, of delicate appearance, ad-

mitted on April 10th, stated that about two years ago he had an attack of rheumatic fever, not so severe as the present, for which he was under treatment for three weeks.

On admission he had been ailing for three days, and his wrist, shoulder, ankle, and knee-joints were red, swollen, painful and immovable. His tongue was yellowish-white; there was slight acid diaphoresis. Pulse strong, bounding, 98; temperature 100° F. The bowels were confined. There were no cardiac complications. He was ordered forty grains of salicin in milk every hour, beginning at noon. At 8 p.m. the pain in the affected joints was much reduced; there was free acid perspiration. As he had not slept for the last three nights, he was ordered fifteen grains of hydrate of chloral, with thirty grains of bromide of potassium. To continue the salicin every hour if not sleeping.

April 11th, 9.30 a.m.: Patient had slept from 10 p.m. till 6 a.m. this morning. Had taken five doses of salicin since his last visit. No pain in any of the joints. Temperature 100.2° F.; pulse 98. To continue the forty grains of salicin every hour.—12th: Perspiration ceased. No pain in joints. Pulse 82; temperature 98.4° F. Slept well without anodyne. To continue the salicin (forty grains) every second hour.—13th: Slept well during the night. Pulse 78; temperature 98.4° F. The bowels were moved naturally.—14th: Limbs free from pain, and can move the joint freely. Skin natural; tongue clean. Pulse 74; temperature 98.4° F. Beginning to feel hungry. To continue the salicin every fourth hour.—15th: Convalescent. Pulse and temperature normal. To continue the same dose of salicin three times a day. Full diet.

This patient will probably be up and walking about in three or four days; and back at his work in eight or ten.

CASE 2.—Catherine C., aged forty-two, married, a strong, well-nourished woman, was admitted on February 23rd. She had been ill for four days. The tongue was white; skin dry; pulse 120; temperature 101.4° F. Both knees, along with left hand and wrist were swollen, hot, painful, and immovable. Ordered thirty grains of salicin every hour, beginning at 11 a.m. This was to be continued until the evening visit; but it was ordered that, if the temperature did not diminish by the third dose, the quantity was to be increased to forty grains. At 5.30 p.m. the temperature was down 100° F., and the pain was nearly gone. To continue the thirty grains of salicin every second hour. As she slept pretty well during the night this could not be done regularly. The quantity, however, was given.—24th: Much better; pulse 94; temperature 99.2°. All pain gone. To continue the salicin every second hour.—25th: All fever gone; pulse and temperature normal. Joints still swollen, but quite movable and painless; appetite returning. The salicin to be taken every fourth hour.—26th: Convalescent. The articular swelling reducing. Ordered salicin (thirty grains) three times a day. Full diet.

March 2nd: Up in the afternoon. The salicin twice a day.—7th: Quite recovered. To continue the salicin once a day for the purpose of preventing relapse.

Remarks by Dr. QUINLAN.—These two cases are offered in the hope that they may aid in promoting the treatment of acute rheumatism by large and frequently repeated doses of salicin, increased boldly until their action beats down the temperature, lowers the pulse, and reduces articular pain. It cannot be too often impressed that the practice of giving salicin in small and distant doses (say fifteen grains every third hour) is simply useless, and too often only serves to give time for cardiac

complication. The essential difference between salicin, the natural product of the willow root, and salicylic acid, the artificial phenol derivative, is that while the latter too often sickens even in moderate doses, you can give almost any quantity of the former. For instance, in the case of the woman C—, it was suggested to me, in March last, that the thirty or forty grain doses of salicin might not be quite safe, and I accordingly determined to try what was the largest dose that could be given. At this time this woman was taking thirty grains of salicin once a day to prevent relapse; and I directed that this quantity should be increased by five grains daily until further orders. This was done, and consequently on Saturday, March 24th, she took eighty grains of salicin at one dose. As this quantity was beyond anything I have seen required in the very worst cases of rheumatic fever, I did not think it necessary to increase it, but simply repeated it on the 25th, 26th, and 27th, without any inconvenience to this patient, who had been detained in hospital for this inquiry much longer than the case required. I have since seen a statement by Korczynsky (Przegl. Ad. Lekarsk., 9, 13) that, as an anti-pyretic, salicin can be given to adults in doses of from six to ten grammes (90 to 150 grains). I do not doubt that this could safely be done, but will hardly be necessary. The forty-grain doses every hour will be found sufficient, and it is likely that in 150-grain doses much of the drug would pass off from the bowels with little, if any, physiological action. Salicin in very large doses is most easily taken by stirring it into a hock glass of milk, which the patient rapidly swallows before it has time to settle down from its suspension. It may also be taken in wafer paper, or even in water, but in this case the bitter flavor is felt. It should always be taken on an empty stomach; after food it often occasions nausea and tinnitus. Its value in acute rheumatism cannot be over estimated, and should the physician get hold of the case early he will be able to conquer it before there is time for cardiac complication, so apt to leave enduring mischief behind it. Salicin is very cheap, its retail price being under one shilling per ounce, and it can be extracted from the bark and green shoots of the willow (at present to be had in any quantity) by a simple process given in Cooley's Cyclopædia, vol. ii., p. 1447. A drop of solution of salicin placed under the micro-polariscope exhibits, with the aid of the selenite stage, a very beautiful display of kaleidoscopic colors, and is thus distinguished from quinine salts, for the adulteration of which it was, up to a few years ago, principally produced. Finally, when the rheumatic sufferer convalesces the salicin should not be dropped too suddenly. For a week it should be given in full doses morning and evening, and for a fortnight once daily; otherwise a relapse may supervene. A notable feature in the salicin treatment is its tonic effect in promoting a steady and rapid recovery of strength and vigor during convalescence.

Walsham descriptive of a rare form of Malformation of the Shoulder-girdle, presumably the persistence of a supra-scapula analogous to the condition met with in the skate, being the second recorded instance of the deformity. The first example had been recorded by the same observers in a paper read before the Society three years ago.

The following is an abstract of the paper on the second Case of Malformation of the Left Shoulder-girdle, with remarks on the probable nature of the Deformity, by Mr. Alfred Willett and Mr. W. J. Walsham. In the 63rd volume of the Transactions is a paper by the authors on "The Dissection of a Specimen of Congenital Malformation of the Bony Thorax, Spinal Column, and Left Scapular Arch, removed from the body of a woman, thirty-two years old, with remarks on the probable nature of the Deformities." The malformation of the shoulder-girdle consisted of a triangular bridge of bone stretching between the spinal column and the scapula. The present paper is founded on a similar malformation in a child eight years old, from whom the bridge-like piece of bone was removed by Mr. Willett, the child making a good recovery. The portion of bone removed was of an irregular triangular form, with a truncated apex. It had an osseous attachment to the spines of the seventh cervical and first dorsal vertebrae, and was connected by a layer of cartilage to the base of the scapula. It measures one inch and three-eighths in length, and one inch and a quarter at its widest part. It was covered by periosteum, and muscular fibres were inserted into it. The malformation is evidently similar to that in the former specimen, but differs in that the union of the bridge of bone to the scapula in the first case was osseous, in the present case cartilaginous—a difference which the authors believe throws additional light on the nature of the deformity. They regard it, in both specimens, as an over-development of the epiphysis which normally exists along the posterior border of the scapula, and consequently as the homologue of the supra-scapular bone of the lower vertebrata. The points that they think favor such a view are—1. The apparent continuity in the first specimen of the bridge of bone with the supra-scapular epiphysis, of which it appears to be an outgrowth. 2. Its cartilaginous attachment in the second specimen to the scapula (central piece). 3. The absence of analogy between these cases and exostoses, and the impossibility of explaining how, if they were exostoses from a vertebra, they could have become secondarily attached to the scapula. 4. The insertion of certain muscles into them, showing that the abnormality occurred at a very early period of development. 5. The abnormal condition, in the first specimen, of the scapula itself, and the presence of concomitant malformation of evident congenital origin. The intimate osseous union of the bridge of bone to the spine might suggest its being a so-called spinal exostosis. It differs from such, however, in that it is not covered with cartilage except where united to the scapula, in its flattened condition, in its growth in only one direction, and in its broad base of attachment to the scapula. The union to both the spine and scapula, moreover, can be better explained on the assumption of its being a supra-scapula. That an overgrowth of the epiphysis may occur is shown by specimens in the museums of the Royal College of Surgeons and St. Bartholomew's Hospital. The epiphysis which normally exists in man at the base of the scapula presents a much higher grade of development in some of the lower animals; in some it remains throughout life as a distinct bone—the supra-scapula, which in some even (the thornback skate) is united to the spine. As the

Medical Societies.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Case of Malformation of the Left Shoulder-Girdle.

THE ordinary meeting of this Society was held on March 13th, Professor J. Marshall, F.R.S., President, in the chair. The evening was occupied by the reading of a paper by Messrs. Willett and

supra-scapular epiphysis in man is admitted by all to be the homologue of the supra-scapular bone of animals, it follows that if the bridge of bone is an overgrowth of the epiphysis it must also be the homologue of the supra-scapular bone. That this epiphysis in man may actually present an abnormal backward development is shown by the specimens referred to. It is advancing, therefore, but one step further to compare the bridge of bone in one specimen to the distinct supra-scapula of the frog, and but one step further still to conceive it united to the spine, as in the skate. On this theory the abnormality may be regarded not as a mere overgrowth of the scapula, but as having existed in its present form, though of course unossified, from the time of the differentiation of the cartilaginous shoulder-girdle from the mesoblast, and therefore as having had an attachment to the spine from the earliest period of its development. Considering the similarity of the primitive cartilaginous shoulder-girdle in all early vertebrates, it would not seem that such a grave departure from normal development was required to produce the abnormality. Analogous processes are not wanting in the human body, as, for instance, the overgrowth of the transverse processes of the seventh cervical vertebra into a cervical rib. If by a forward extension the transverse process, the homologue of a rib, may, as in birds, be developed into an actual rib, why may not the scapula epiphysis, the homologue of the supra-scapula, be developed by a similar but backward extension into an actual supra-scapular epiphysis, as in reptiles and fish? Given a cartilaginous union between the scapula and the spine there is no difficulty in explaining how the ossific centres in the spinous process and supra-scapula would meet and become fused, any more than in the analogous process of the union of the epiphysis and diaphysis in an ordinary long bone. The probabilities of the malformation having existed from a very early period of development are strengthened by the following facts:—1st. The attachment of the muscles into the bridge of bone. 2nd. The rudimentary condition of the scapula itself in the first specimen. 3rd. The concomitant malformations of the spine, ribs, and clavicle, which were shown in the former paper to have occurred at a very early period of the development of the embryo.—At the close of the paper the child was exhibited to the Fellows by Mr. Willett, and it was seen that the scapula had regained its natural mobility.

The President, in inviting discussion upon the paper, drew attention to the interesting fact of two examples of this hitherto unrecorded deformity having occurred to the authors within a few years. The question of its origin, whether it was a reversion to a type present in the lower vertebrates, or whether it was an aberrant osseous formation between the spine and the scapula in the position occupied by muscles, was important, and the evidence adduced favored the former view.—Mr. Howes said that modern inquiry pointed to the direct descent of mammals from the amphibia, and he referred to the resemblance between the shoulder-girdle of echidna and that of the amphibia in illustration of this; the cervical ribs in that animal also persisting during life. Recent embryological researches had shown that the limb girdle is developed from the limb itself, so that any attachment of the former to the spine must be secondary. In the skate the ossified supra-scapular bone is fixed to the unossified spine, which is strengthened by a vertebral plate at this place. He alluded to many developmental affinities between amphibia and mammalia, as in the hyoid arch, the Eustachian cartilage, the mandible (which Professor Parker has lately found in the fetal mole and in the

platypus to be composed of splint-like portions as in the lizards), and the parisphenoid—an amphibian structure, of which a relic has been found by Professor Parker in the creeping lemur. Such facts supported the author's view of the abnormality they described being the homologue of the supra-scapula. Its fusion with the spinal column depended probably upon the necessity of its affording sufficiently firm attachment for the neck muscles.—Professor Thane assented generally to the authors' conclusions in that in each of the instances it was an example of a greatly developed supra-scapula. The dissection of the former specimen showed that it was not an instance of ossification in muscles passing between the spine and shoulder-girdle. Indeed, the similarity to the supra-scapula of the frog was very striking. That the structure should ossify earlier than the epiphysis usually does was not surprising, for when a part ordinarily small and vestigial is increased in size its developmental processes are hastened, as seen in the caracoid. Its union with the spine was more difficult to explain; and the cartilaginous connection with the scapula made it almost impossible to believe that it was primarily developed from the spinal column. Atavism was a natural explanation for its occurrence; and certainly in many mammals the supra-scapula is very well developed, and cartilaginous wholly or in part; but he doubted whether its connection with the spine could be so explained. This united condition in the skate was doubtless related to the great development of its upper limbs; and, moreover, the fact which Mr. Howes had pointed out as to the shoulder-girdle being developed from the limb, and separated by the muscle-plates from the vertebral column, rendered the explanation of this union the main difficulty to be explained.—Professor Curnow agreed with Professor Thane that the difficulty lay not in its connection with the scapula, but with the spine, and the parallelism to the skate increased the difficulty. Was there any evidence of hereditary transmission of the malformation?—[The Hon. Secretary (Mr. B. Hill) read a letter from Professor Milnes Marshall, expressing his regret at being absent, and his inability to agree with the authors' morphological conclusions, partly on grounds of theoretical improbability, as regarded the skate-like type of shoulder-girdle, and partly from the fact that in both recorded instances the malformation was on one side only. The accompanying deformities in the first case would tell against the authors' theory, unless it could be shown that these malformations were of the nature of reversions to an ancestral type. The cases might be explained by pathology rather than by morphology.]—The President was also struck by the unilateral character of the malformation, and that in both cases it was on the left side. The structure of the bony plate, however, showed it to have been formed in cartilage, and not by ossification of fibrous or muscular tissue. It seemed more likely that the fusion with the spinal column was due to attrition and pressure rather than referable to a morphological condition of the lower animals.—Mr. Willett, in reply, said that Mr. Howes' remarks strongly corroborated the view of reversion affording the best explanation of the condition. The great difficulty which had been raised seemed to be cleared away by Mr. Howes' statement, that the ossification must grow from without inwards, which excluded the idea of the structure being spinal in origin. Its connection with the spine might fairly be explained by contact and attrition. He was unable to give any facts as to heredity; the child was the only one, and the mother died early. As to its unilateral disposition, the small number of cases observed

deprived that objection of much weight. He regretted Professor Milnes Marshall's absence, as he might have explained why he regarded the condition pathological rather than morphological. In conclusion, Mr. Willett expressed his great obligation to Mr. Walsham for the labor he had bestowed on the paper.—Mr. Walsham claimed Professor Milnes Marshall and Professor Flower as supporting the possibility of a supra-scapula element being found. Analogous instances of reversion are often one-sided. In the first case, the concomitant malformations lent great support to the view they maintained, and Professor Parker, when he saw that specimen, at once recognized its similarity to the shoulder-girdle of the skate.

On Cases described as "Acute Rickets" (combination of Rickets and Scurvy).—Subperiosteal Hæmorrhage, probably Scorbutic, of three Long Bones in a Rickety Infant.

The ordinary meeting of this Society was held on March 27th, Mr. W. S. Savory, F.R.S., Vice-President, in the chair. A very exhaustive paper, communicated by Dr. Thomas Barlow, upon the subject of infantile scurvy and its association with rickets was read in abstract, and was followed by a paper relating an example of the disease by Mr. Page. Dr. Hale White's paper on a case of scurvy with retinal hæmorrhages and dilatation of the heart, read at a former meeting, was also read in abstract, time not permitting of its discussion on the previous occasion.

The following is an abstract of the paper on Cases described as Acute Rickets (combination of Rickets and Scurvy), by Dr. Thomas Barlow. The paper is a contribution to the study of a disease occurring in young children, of which several cases have been recorded in recent German and English medical literature, but of which, with one exception, no account of the morbid anatomy has hitherto been given. The writer first narrated a typical case, then gave an analysis of the principal symptoms observed in the recorded cases and in other cases of his own, then the results of some post-mortem examinations, and finally discussed the etiology and affinities of the disease. The typical case was given in full detail. The boy, aged fifteen months, was of a pale, sallow complexion, fat, but flabby. His rectal temperature was 101°, there was no nervous or visceral disease except that the liver was larger than normal. He was continually moaning, and when approached and touched screamed violently. The dominant symptoms were in the limbs, the right wrist was dropped, and the left thigh continually drawn up; the ribs were beaded, but there was no grooving of the thorax; the left thigh and leg were tightly swollen, assuming a cylindrical shape; the epiphyses of the knees were enlarged, and there was a tendency to knock-knee. There was profuse sweating about the head. The boy was a first child, born slightly before term, and seemed vigorous for the first six weeks, during which time he had his mother's milk, but since its failing he had been deprived of fresh food, his diet consisting of the various infant foods of Nestle, Robb, etc. The child sat up well, and stood with assistance at thirteen months old, but five weeks ago he ceased to do either, the left leg and ankle being swollen, and the child shrieking if approached. The child was taken to a well-known bonesetter, who said that one of the bones of the spine was out, and a presumed operation to set it right was performed, but as no explanation was given of the swollen wrist, dropped right hand, and condition of left thigh, further opinion was taken. The child was

obviously the subject of moderate rickets, and the opinion was formed that under the periosteum of the left femur and tibia there was an effusion of blood, and that the extreme tenseness of the limb was due to blood extravasation in the deeper muscular layers with the serum filtered into the more superficial parts of the limb, and the view was held that the boy was suffering from the supervention of scurvy on rickets, though with no sponginess of the gums. The treatment suggested was to surround the whole of the left lower limb and the right leg with wet compresses, which had been thoroughly wrung out, surrounded with dry clothes closely applied. A complete change in diet was made: to the juice of raw beef sweetened a little, cow's milk, strained gruel, barley water, and orange juice. It was ordered that the boy's crib should be placed near the fire, and the window opened wide for free play of fresh air. A great change occurred during the treatment. He was quieter and took his fresh food greedily, had healthy evacuations, and the tension of the left lower limb was less. The improvement was progressive. The urine became clear and free from albumen, and from excess of phosphates. The swellings of the wrist and lower limbs subsided, and at the end of a fortnight he made slight efforts to raise himself and move his limbs about. At the end of a month gentle shampooing with oil, and douches of tepid and then cold water, were commenced. No change was made in diet except substitution of beef-tea for raw meat juice, and a small piece of underdone meat in muslin to suck. His medicine was one teaspoonful, and then two teaspoonfuls, of cod-liver oil daily, and an occasional powder of rhubarb and soda. Within eight weeks he got on his knees, and could stand with a little support. He was of a ruddy color, and his skin and muscles felt firm. The author then gave an analysis of the principal symptoms in thirty cases, of which nineteen have been published (principally in Germany), the majority under the name of "acute rickets," and one under that of "infantile scurvy." The first English case was under the care of Mr. Thomas Smith at the Hospital for Sick Children, described under the provisional title of "hæmorrhagic periostitis." Other cases had been described by Dr. Gee, as "osteal or periosteal cachexia," and two by Dr. Cheadle, in which spongy gums were a marked feature, for which and other reasons Dr. Cheadle held them to be a combination of rickets and scurvy. The ten cases of the author led him to substantially the same conclusion. The author then gave an analysis of the important symptoms, the post-mortem appearances, the etiology and affinities of the disease with the ordinary form of rickets, congenital syphilis, etc. The evidence shows the ordinary form of rickets to be present in a considerable number of the cases, though in some the symptoms were very slight. It shows also that there is no affinity with acute periostitis, hæmophilia, or purpura. The parallelism of the disease with scurvy was shown both on anatomical and clinical grounds, and after giving a summary of the diet adopted in the recorded cases, the author came to the conclusion that the characteristic features of the so-called acute rickets are really due to "scurvy."

The next paper read was upon Subperiosteal Hæmorrhage, probably Scorbutic, of three Long Bones in a Rickety Infant, by Mr. Herbert W. Page. The author recorded the case of an infant, aged nine months, extremely wasted, pale and ill, who was sent to him by Dr. Taylor, of Willesden, and who presented enormous enlargement of the shafts of the left femur and tibia, and of the upper third of the right tibia also. The swelling

had been coming on and gradually increasing for about a month. The neighboring joints were not affected, and there was no superficial sign of inflammation. Beading of the ribs and rickety enlargement of one radius led to the belief that the condition was in some way due to rickets, and this supposition was also based on the fact that the child had from birth been fed for three weeks on Swiss milk, and after that almost entirely on Nestle's and Savory's foods. There was no history of syphilis, and in the absence of general fluctuation no certain diagnosis was made. A trocar and cannula passed at one point in the thigh, where there was doubtful fluctuation, gave exit to a few drops of sanguineous fluid, the bone being found bare. Incisions were therefore made through the periosteum of both thigh and leg, and large blood-clots, which had to be broken up with the finger before any part of them could be removed, were found lying around the shafts, the periosteum being stripped up therefrom throughout their entire lengths. Being now properly fed, the child, whose recovery had seemed well-nigh hopeless, began at once to improve, the blood-clots were gradually expelled, there was little or no suppuration, the wounds healed, and when seen three months afterwards the affected bones had resumed their normal size, and the periosteum its natural position in contact with the shafts. There is no hæmorrhagic diathesis in the family. The author referred to the difficulties in diagnosis presented by this case, especially in the absence of fluctuation, which was doubtless due to blood-clot being tightly packed between periosteum and bone. He is now inclined to regard the disease as scorbutic rather than rickety, and the hæmorrhage as the more essential element of the pathological condition than inflammation of the periosteum. The child had been reared on scurvy diet. Periostitis is almost unknown, even in the worst cases of rickets. There was no sign of inflammation either in the neighboring joints or in the skin; and it is, moreover, noteworthy that both periosteum and bones have survived the attack. Such could hardly have been the issue of an acute hæmorrhagic periostitis, even though the hæmorrhage, as a local bloodletting, might have conduced to the safety of the periosteum. He referred to other cases, of which, indeed, there is only one definite example on record in support of this doctrine. A case was recorded by Mr. Thomas Smith in vol. xxvii. of the Pathological Society's Transactions as "Hæmorrhagic Periostitis of the Shafts of several Long Bones with separation of Epiphyses," where, after death, the shafts were found surrounded by blood-clots underneath the periosteum, and in which there were numerous hæmorrhages in the muscles also, with a large hæmorrhage in one lung, hæmorrhages, in fact, like those ordinarily seen in scurvy. In one of three cases recorded by Dr. Cheadle of "Scurvy Supervening on Rickets in Young Children," in addition to bleeding gums and other usual signs of scurvy, there were "hard swellings deeply seated in the flesh of each thigh, and the shafts of the long bones felt enlarged and swollen." The author had little doubt that in that case also the enlargement was due to subperiosteal hæmorrhage. The child had been fed on a scurvy diet, and the state of the gums very clearly told what unnatural agents had been at work. In his own case the diet was a distinctly scurvy diet, lacking every kind of fresh food, and he trusted that the record of it may lead to a surer diagnosis and better treatment in other cases where the absence of swollen and bleeding gums deprives us of an all-important clue to the nature of the malady.

Dr. Stephen Mackenzie believed that the valu-

able papers that had been read would go far to remove the difficulties which beset the subject. He referred to two cases of the kind under Mr. Waren Tay's care, of which he had made the post-mortem examinations. One was an infant about four months old, who had been brought up on artificial food and London milk. There were extensive subperiosteal hæmorrhages around several of the long bones and the ribs; and also extravasations in the gums at the site of the non-erupted teeth, a condition differing from scorbutic sponginess, but not uncommon in these cases. In another case he had seen extravasation into the orbit, and beneath the skin of the arm. The second case he had examined post mortem was marked during life by a swelling over the lower end of the femur, which had been noticed for two months. The infant was eight months old, and the limb was helpless. The condition was thought to be syphilitic, and Mr. Tay prescribed grain doses of iodide of potassium. After two doses had been given, some ecchymosis appeared about the orbit, but no further purpuric manifestations, although the iodide was continued. Other swellings appeared on the limbs, and the child became marasmic and died. The periosteum was detached from the ribs by hæmorrhage, and the same condition occurred to several of the long bones. Hæmorrhages also occurred in the lungs, intestines, and kidneys, and the case was complicated with recent peritoneal tuberculosis. These cases, then, lent support to the views advanced by the authors of the papers. Dr. Mackenzie laid stress on the fact that purpura was not a disease *per se*, but dependent on various conditions. Referring to Dr. Hale White's case, he mentioned that for some years past he had sought for retinal hæmorrhages in cases of scurvy at the Greenwich Hospital, but had never met with them except in that one case. He attributed this to the fact, insisted on by the author, that the occurrence of retinal hæmorrhages is determined by a certain degree of anæmia. His own experience went to show that retinal hæmorrhages are not met with unless the corpuscular richness falls below 50 per cent., and that no matter what the disease producing the anæmia is. He had found such hæmorrhages in cases of hæmatemesis, where the blood standard reached this low level; and in idiopathic progressive anæmia the corpuscular richness is much less than this.—Mr. Macnamara remarked that in the tropics retinal hæmorrhages were not uncommon in scorbutic disease. He had often found them in natives who, after repeated attacks of intermittent fever, became scorbutic; and especially in scorbutic dysentery, where the ulceration of intestine is secondary to hæmorrhage in the submucous tissue. He had no doubt as to the scorbutic nature of Dr. Barlow's cases, and thought it remarkable that in no case did periostitis ensue on the subperiosteal hæmorrhage. He suggested whether some of the cases of acute suppurative periostitis, or acute necrosis of children, might not be secondary to the breaking down of clots found as described. Speaking of the relation between syphilis and rickets, he had no doubt that the state of malnutrition upon which rickets depended might be brought about by inherited syphilis. It might be quite correct, then, to ascribe some of these changes to syphilis as one of the factors to which rickets and the scorbutic element were superadded.

Mr. R. W. Parker thought it remarkable that so few cases should be recorded if the condition depended so much upon improper diet and hygiene, to which so large a number of children in London and elsewhere were subjected. For although young people do seem to enjoy an immunity from scurvy, yet the disease is very rife in the Russian

foundling hospitals. Most writers regard the bone lesions and periosteal lesions as late manifestations of scurvy and secondary to profound cachexia; but in the cases related that evening these lesions seem to have been sometimes observed in children otherwise robust, and the development of the lesions to have been remarkably rapid. Nor did the cases exhibit the putrescence so common in scurvy, and the condition of the blood was not that usually described in this disease, for it coagulated firmly. He had made post-mortem examinations on three cases of "acute rickets," in which the bones were greatly softened, but there was no scorbutic appearances.—Mr. J. H. Morgan remembered Mr. T. Smith's case, with which Dr. Barlow's cases were identical. The extremely vascular condition of the medulla of the shaft and the epiphysis in that case suggested changes in the vessels of the medulla itself, and might explain the occurrence in that case of fracture of the femur at a point below the epiphysis. He thought the evidence of survy was satisfactory, and it was interesting that in all the cases the scurvy was superadded to a rickety condition. The absence of symmetry in the distribution of the lesions was a point of distinction from the bone changes of congenital syphilis. Dr. Drewitt said that all agreed as to milk being antiscorbutic, and pointed out that in London there must be thousands of children fed on condensed milk alone, without suffering from scurvy. He suggested that ships should, in addition to lime juice, be also well supplied with condensed milk.—Mr. Savory thought that Mr. Page's case showed that acute periostitis alone would not suffice to produce necrosis, for in that case the whole of the shaft of the bone was detached from the periosteum by hæmorrhage; yet the bone retained its vitality. This seemed conclusive evidence in support of the view he and others held that in cases of suppurative periostitis followed by necrosis there was osteitis as well.—Dr. Barlow, in reply, said that he had frequently observed in these cases small ecchymoses on the gums on the sites of the growing teeth. One case had also ecchymosis of the eyelids, and a temporary partial ptosis. He had also seen the hæmorrhage around the ribs, a point observed by Poupert in the seventeenth century. The visceral hæmorrhages observed by Dr. Mackenzie were important additions, and in Mr. Smith's case there was a small hæmorrhage in the lung. Tuberculosis not infrequently developed in marasmic children. He quite concurred that the term "purpura" should not be held to denote a distinct disease, and remarked that the subjects of purpura suffered occasionally from temporary swelling and tenderness in the legs, suggestive of deep-seated extravasation. He would not like to say that these subperiosteal hæmorrhages never passed on to suppuration, but he had not yet seen any evidence of suppuration. In one case a small fluctuating point appeared above an epiphysis, which he attributed (from the conditions found in other cases post mortem) to accumulation of serum in the more superficial parts of the limb. In a case, which, however, hardly seemed one of this class, there was partial suppuration. Although the shaft of the bone is detached by the hæmorrhage, it is probably nourished through the epiphysis. He agreed that syphilis might be regarded as one of the factors producing rickets; but there was no evidence of syphilis producing hæmorrhage. He admitted the force of Mr. Parker's argument as to the paucity of such cases, notwithstanding the prevalence of the supposed etiological conditions, but believed that minor manifestations of scurvy were far more common in civil life than was admitted. Dr. Cheadle believes that many

cases of stomatitis in children are due to scurvy, and they certainly soon get well on antiscorbutic treatment. Many of these cases may be overlooked, being regarded as rickets, the extreme tenderness and great feverishness of the children being obstacles in the way of thorough examination. Young people do suffer from scurvy, as the experience of the Russian hospital, mentioned by Mr. Parker, showed. Aching in the limbs is given by writers on scurvy as one of the earliest symptoms; and the blood is by no means invariably altered in appearance. Although London children are often brought up on a diet capable of inducing rickets—e.g., bread and butter—they are also largely fed upon potatoes, which are antiscorbutic. In the paper he had mentioned that some of the children had an extreme aversion to meat and vegetables, and such facts may serve to explain why in one family one child will suffer from scurvy and others from rickets. The difficulties were not greater than in the adult, and in some the element of idiosyncrasy must be borne in mind, some people escaping scurvy although placed under precisely the same conditions as those who suffer. The great vascularity of the shaft and medulla referred to by Mr. Morgan is present in well-marked rickets, and he rather attributed the occurrence of fracture below the epiphysis to the fact that the structure of the bone is less compact there, and more brittle, so that when the periosteum became detached, and the bone was left unsupported, it gave way at this spot on slight movement. Syphilitic lesions were symmetrical, but so occasionally were these under consideration. The main points of distinction from syphilitic lesions lay in the age of the subject and in the fact that none of the children were fed at the breast. Dr. Black used to treat his cases of scurvy at the *Dreadnought* on milk alone, and there was no doubt as to its antiscorbutic properties; but condensed milk—valuable as it is—certainly does not protect from scurvy. Fresh food was requisite.—Mr. Page said that his paper was mainly of interest as affording confirmation of the points advanced so fully by Dr. Barlow. No doubt his case would have got well had he adopted the measures followed by Dr. Barlow; but he was urgently pressed to relieve the child, and great relief was given by the incisions. He fully agreed with Mr. Savory that the necrosis so often seen with acute periostitis was due to inflammation of the bone itself; and the vitality of the bone in his case was tolerably conclusive that the condition was not one of hæmorrhagic periostitis. The fact of the blood coagulating was not fatal to the scorbutic theory, for the same happened in well-marked cases of scurvy. It was difficult to say why in some children improper nourishment should lead to rickets and in others to scurvy; but in his case the rickets was not marked, and the child had been most improperly fed from its birth up.—Dr. Hale White said that since his paper was read he had found that Dr. Buzzard, in his article in "Reynold's System of Medicine," mentions the fact of cardiac dilatation in scurvy, although he does not ascribe any symptoms to it such as those observed in his (Dr. White's) case.

Nævus of Rectum.—Recurrent Cancer.

The ordinary meeting of this Society was held on April 10th, Mr. J. Marshall, President, in the chair. The following gentlemen were elected Fellows of the Society:—Mr. H. Royes Bell, Mr. D. W. Buxton, Mr. W. Edmunds, Mr. V. Horsley, Mr. E. Land, Dr. Angel Money, Dr. C. D. F. Phillips, Dr. T. M. Wilkinson, and Dr. W. E. R. Wood. Neither of the papers read afforded much scope for discus-

sion, as one was an account of an almost unique case, and the other was a combination of pathological speculation and accepted surgical doctrine.

Mr. E. T. Barker contributed a paper on a case of Nævus of the Rectum in the Adult, proving Fatal from Hæmorrhage. This case was offered for special consideration on the following grounds: 1. On account of its rarity; no similar case being known to the author after careful search. 2. On account of the gravity of the condition in this special instance, in which, in a particularly strong and healthy adult, slow death from bleeding was the result. All the symptoms usually met with in those dying from loss of blood appear to have been present here. Beyond these there were few special symptoms noticed as dependent on the condition. The patient, whose earliest symptom was an attack of diarrhoea accompanied by great loss of blood, usually suffered from constipation, and was obliged to strain much during defecation. Sometimes, however, he had intervals of diarrhoea, always with great loss of blood, and felt no pain and lost no flesh, and there was no particular discharge from the rectum except during the attacks of bleeding. 3. From the fact that a diagnosis of the condition was made by inspection of the rectum with a strong light. This was thrown up the bowel by a forehead mirror from a powerful lamp, and through a large vaginal speculum, which could always be introduced under chloroform. By this inspection the mucous membrane of the bowel was seen to be marked by smooth longitudinal folds, mottled with a peculiar purplish tint. On these purplish folds were three shallow ulcers whence blood flowed freely. The patient gradually sank, in spite of various remedies, and died from loss of blood. Post mortem, the wall of the rectum was found to be much thickened in the lower four inches and a half of its length by nævoid growth in its walls, on the rugæ of which were the three shallow ulcers before described. The body in other respects was healthy and well developed, but almost free from blood.—Mr. Howard Marsh referred to the case of a girl, aged ten, lately under his care in the Children's Hospital. Since the age of two she had suffered from repeated, and sometimes severe, hæmorrhages from the bowels. Under chloroform and with the aid of a speculum, a nævoid growth was seen in the lower part of the rectum completely surrounding the bowel. This was treated by several applications of Paquin's cautery, which relieved the symptoms but did not cure the growth.—Mr. Stanley Boyd had seen Mr. Barker's case on his first attendance at the hospital. On examining the rectum he found it full of blood, and did not detect the ulcers subsequently noticed. When he passed a speculum he was unable to pass anything larger than a No. 2 rectal bougie into the sigmoid flexure, and on withdrawing this fetid blood and a little feces came down into the speculum; he therefore had diagnosed the case as one of cancer of the sigmoid flexure. Microscopically the growth was a cavernous nævus involving both the mucous and submucous tissue.—Mr. Marshall remarked upon the great rarity of such a case. He thought it would have been very hazardous to have treated it with the actual cautery; the man's sudden death prevented any radical measures being tried while the patient was in the hospital.—Mr. Barker drew attention to the fact that immediately after death the body exhaled a horribly fetid smell like that described in cases of scurvy with great anæmia.

Mr. Harrison Cripps contributed a paper on some points connected with Local Recurrence of Malignant Disease, of which the following is an abstract:—He commenced by criticising the view commonly expressed that local recurrence takes

place in the cicatrix of the wound, and pointed out that it is rather in the skin and subcutaneous tissue adjacent to the cicatrix that the occurrence is often observed. A paper published by the author in the Pathological Society's Transactions of 1881 was referred to, in which microscopic evidence was produced, illustrating the view that, as regards malignant disease of the rectum, whether found in the mucous or in the submucous coat of the bowel, it was originally formed of cells derived from Lieberkühn's follicles. A theory founded upon these specimens was also suggested that the formation of leucocytes was one of the normal functions of the intestinal epithelium. Two cases were narrated in which recurrence of malignant disease undoubtedly first showed itself by cancerous nodules originating in the deeper layer of the cutaneous epithelium by the side of the cicatrix—that is to say, in a part of the skin that has not been removed at the time of operating. After referring to the views of Brodie and other surgeons as to the desirability of removing the entire mammary gland, notwithstanding that the cancer may involve only a small portion, the author advocated that the same principle should be applied to the superjacent skin. The theory upon which the surgeon advocates the removal of the whole gland tissue is that, notwithstanding a great portion of it appears sound, the epithelial lining of the ducts and acini are in reality already infected, and only require time for cancerous growth to become manifest; the epithelium within the gland being in direct continuity with that covering, and the superjacent skin being originally derived from it by involution. Thus the cutaneous epithelial cells lying over the gland are as liable to be implicated as those within it. The author, of course, recognized that it is the universal practice of surgeons when operating for mammary cancer freely to remove any skin that appears to be implicated, but he suggested that even in cases where the skin is soft and supple possibly longer immunity from recurrence might be obtained by its wide and free removal than by being satisfied with a mere elliptical portion involving the nipple.—Mr. Alban Doran referred to Rindfleisch's view of the origin of red corpuscles from the nuclei of myeloid cells, and said this was homologous with Mr. Cripps's theory of the origin of leucocytes.—Dr. Creighton said that scar tissue was in cases specially prone to become cancerous. But recurrent nodules were often found widely removed from the original tumour. In all such cases that he had examined he had not found the tumour continuous with the rete mucosum.—Mr. Butlin reminded the Society that Mr. Charles Moore had long ago advocated the wide removal of cancerous growths, and more recently Dr. S. W. Gross, of Philadelphia, and Mr. Banks, of Liverpool, had carried out this practice with far better results than surgeons had usually obtained in the treatment of this disease. Recurrence depended upon portions of affected or infected tissue being left behind at the time of operation. He could not quite follow Mr. Cripps in his more speculative views as to the development of leucocytes and cancer.—Mr. Marshall asked for actual demonstration of the correctness of Mr. Cripps's views of the relation of intestinal epithelium to leucocytes. He had never imagined that cancer really originated in scar tissue, but rather in its immediate vicinity, and that scar tissue was a very favorable soil for it to grow in. All surgeons were now agreed that the more freely cancers were removed the better; and he referred to the opinion of the late Mr. Clover, who had witnessed very many operations, as corroborative of this view. In the works of Dr. John Brown, of Norwich, a description of an opera-

tion for the removal of the entire breast and all the covering skin is given, and is stated to be the best treatment for cancer of that organ.—Mr. Cripps replied that having raised, and, he thought, demonstrated, his pathological views before the Pathological Society he had not thought it right to repeat that demonstration there. Only by the cells themselves being carried away from the primary disease could such a fact as the secondary formation of adenoid cancer in the liver be explained. He was not aware of the work of Gross and Banks alluded to by Mr. Butlin; but he thought it was important to call attention to the necessity of removing cancerous tumours more freely.

Mr. Stanley Boyd showed microscopical sections of Mr. Barker's case of Rectal Nævus of the Liver, and of a Nævus from the Forehead.

The Society then adjourned.

MEDICAL SOCIETY OF LONDON.

President's Address.—Poisoning by Citrate of Caffeine.—Diffusion of Medicinal Agents in the Atmosphere.

At the meeting on March 12th, the chair was taken by the newly elected president, Sir Joseph Fayrer, who gave a brief opening address. After thanking the Fellows for the honor conferred upon him, and referring to the variety and value of the work done by the Society, and the satisfactory condition in which it was at present, he alluded to the new extension of the buildings, the accomplishment of which had been aided by the liberal manner in which a former President, whose munificence has made his name familiar as a household word, had come forward to their help, and he trusted that restored health would one day permit them to meet Sir Erasmus Wilson in the rooms which owe so much to his liberality. Sir Joseph then spoke of the catholic aims of the Society, and of the work done in the past year, paying a warm tribute to the Lettsomian Lecturer, Dr. Sansom. Among the subjects especially demanding attention was that of the causal relations of minute organisms to disease, of which they had already had contributions from Drs. Whipham and Heneage Gibbs as regards tuberculosis, about which much still remains to be determined. The probability that many other diseases depend on micro-organisms adds greatly to the necessity for continued observation and the true interpretation of observed facts. The subject of antiseptic surgery and its relation to the germ theory still afforded field for inquiry. The subjects of parasitic diseases, of the etiology of fevers, of tropical diseases, the value of alcohol, the histogenesis of cancer, were indicated as matters which were still open questions for debate, and the address concluded with an exhortation to the Fellows to contribute by their communications to the scientific and practical advancement of medical knowledge.

Dr. Routh read notes of a case of Poisoning by Citrate of Caffeine. The drug had been prescribed in drachm doses three times a day for the relief of severe headache in a man under treatment for debility. Bishop's effervescent preparation was intended, but the pure drug was sent. Fifty minutes after taking one powder he complained of burning sensation in the throat, of giddiness; there was vomiting and purging with pain in the belly. He then became almost paralyzed, and was affected with tremors, but his intellect was clear. Dr. Routh found him an hour later collapsed; pulse about 120. Ipecacuanha was given as an emetic, but failing to act, some animal charcoal, with nitrite of amyl and ether, was given. Vomiting

subsequently took place, and ammonia, alcohol, and nitro-glycerine were given. For some hours he remained much depressed, and did not rally completely till 1.30 a.m. next day, or nine hours after taking the caffeine. Nitro-glycerine in one-minim doses was given every two hours, with digitalis, and in about three days he recovered to his former state.—The President did not know of any similar case in man. Experiments had shown that the citrate of caffeine stimulated involuntary muscles. In rodents it was only slowly fatal. It resembled theine and the alkaloid of coca and Paraguay tea in increasing the power of muscular effort.—Dr. Thorowgood had found the drug useful in cases of asthma. In a severe case he treated two years ago a threatened attack of asthma passed off after one dose (one grain) of the citrate of caffeine had been taken, but extreme faintness speedily set in. Later Dr. Thorowgood found that the attacks were due to cardiac disease, and the patient died eventually in syncope, so that the former syncopal attack was probably not due to the caffeine. He had seen no evidence of the alleged tetanizing effects on the heart of this alkaloid.—Dr. Gilbert Smith would have preferred a less depressing emetic than ipecacuanha in such a case. He had given citrate of caffeine in cases of cardiac and renal disease, and in asthma, for which it was very useful. Caution was necessary in cardiac cases, for he had known severe collapse follow even small doses.—The President alluded to the value of strong coffee in opium poisoning, and the superiority of coffee to alcohol as a stimulant. Was caffeine, which is closely allied to quinine in having very little carbon, concerned in this action of coffee? Did Dr. Routh observe whether the paralysis passed into a tetanic condition as seen in animals?—Dr. Routh was aware of the experiments referred to and others in which theine was used. There were no convulsions, but only marked muscular tremors; and there was paralysis, but no tetanus. He feared to give sulphate of zinc or copper.

Dr. R. Lee read a paper on the Diffusion of Medicinal Agents in the Atmosphere. He remarked that the principles on which antiseptic surgery was founded might be extended to the treatment of pulmonary diseases, provided that the difference between diffusion in a vapor and a fluid was kept in view. In the volatilization of any antiseptic or medicinal agent it is necessary that the water with which it is mixed should be evaporated, and that no practical use resulted from simply mixing the substance with hot water and inhaling the steam. Dr. Lee stated that the rate of volatilization of any substance when boiled with water depends on its own boiling-point, its specific gravity and readiness to mix with water. In the case of the oil of the eucalyptus globulus, by mixing alcohol with it the rate of evaporation could be controlled, for though its boiling-point was 320°, its specific gravity was less than water, and it volatilized when mixed with it much more rapidly than the water. Carbolic acid has the singular property of volatilizing in exactly the same proportion as the water with which it is mixed, and thus it is the most suitable for all antiseptic methods of treatment.—Dr. Cullimore spoke of the value of sending patients to places where the air is naturally charged with certain emanations. In Iceland freedom from phthisis might be due to the sulphur in the air.—Dr. Dawtrey Drewitt asked Dr. Lee if he was quite sure that acetic acid is not volatilized when mixed with boiling water.—The President pointed to the fact that the air of London was permeated by sulphurous acid.—Dr. Lee, in reply, pointed out that burning was not volatilization, but destruction.

Foreign Body in the Bladder.—Endemic Hæmoptysis and Distoma Ringeri.

At the meeting of this Society on March 19th, Sir Joseph Fayrer, President, in the chair, Mr. Hugh Smith related a case of Foreign Body in the Male Bladder, in which Bigelow's operation was performed. A Suffolk farmer, thirty-nine years of age, was admitted into King's College Hospital on Dec. 11th, 1882, with symptoms of stone in the bladder. On Dec. 16th lithotripsy was performed; the calculus was easily friable, but it choked the blades of the lithotrite. Bigelow's apparatus was used, but it did not answer well at first. The lithotrite was reintroduced, and a piece of straw a little more than three inches in length was removed from the bladder. Bigelow's apparatus was again used, and several fragments were washed out. A few days later Mr. Henry Smith removed another piece of straw, two inches and a half long, with a light scoop lithotrite. Several large fragments of stone passed during micturition, some of them showing a distinct groove into which the foreign body fitted. Mr. W. Rose extracted some fair-sized fragments of calculus during Mr. Smith's absence, and shortly afterwards the patient was discharged well. In answer to questions, the patient said that he had passed a stalk of green grass down the urethra one day last summer, because he was suffering from retention of urine. He removed, as he thought, the whole of the grass passed; but soon afterwards he noticed a pricking sensation in the bladder, and observed that his water looked like porter. Had Mr. Henry Smith known the above history before operating, he would have taken other means to remove the foreign body. A light scoop lithotrite would have been used instead of a large and powerful crushing instrument. Bigelow's apparatus would not have been employed owing to the probability of the eye of the catheter becoming blocked, as it undoubtedly was, by the tough ligulate of the foreign body.

Mr. Pearce Gould exhibited one of Bigelow's latest Evacuators, and explained the several improvements introduced into it. He also showed the photograph of a stone weighing 1380 grains which had been removed by lithotripsy at one single sitting by Professor Bigelow. He suggested that if Mr. Henry Smith had used one of the modern patterns of lithotrite he would not have had so much trouble by the clogging of the instrument.—The President was reminded of a case of stricture, where the patient, in withdrawing a gum elastic catheter, which he had learnt to pass himself, left half of it behind. Sir Joseph failed to extract it, but a year later he removed by lithotomy a large phosphate stone, which developed around the broken catheter. In India stone is remarkably prevalent, but in those days lithotripsy was hardly known. Once when operating for stone, on putting his finger into the bladder, it was pricked, and on withdrawing it, a large needle was found transfixing the stone. He was unable to say how the needle entered the man's bladder.

Dr. Manson read a paper on *Distoma Ringeri* and Endemic Hæmoptysis.—Dr. Cobbold said that when the parasite was sent to him for identification he at once recognized it as a genuine lung fluke and thus confirmed Dr. Manson's previous surmise. He described it in the *Quekett Club's Transactions* as *Distoma Ringeri*. The parasite reminded him of the *D. compactum*, which he, many years ago, discovered in the lungs of an Indian ichneumon. The position of the suckers and the form and branching of the vitellaria at once pointed to its true nature. It resembled also the *D. Rudolphi* discovered by the celebrated Austrian

traveller in the lungs of the Brazilian otter, and the more recently discovered *D. Westerni* described by Dr. Hebert in the *Achiv für Mikroskop. Anat.*, vol. xix. In most of these animals the flukes are encysted in pairs, generally lying immediately beneath the pleura, and as we descend the scale of vertebrate hosts, the flukes lose the more or less characteristic oval or oblong figure, becoming more or less attenuated, as in *D. Bossi* and *D. cylindricum*. (Dr. Cobbold exhibited the specimen of *D. Ringeri*, and also lung flukes from the ichneumon, frog, and snake.) He thought Dr. Manson had done excellent work in pointing out the parallelism subsisting between endemic hæmaturia and endemic hæmoptysis. The subject was of great importance in relation to tropical disease, and he hoped that the remedies employed would be efficacious, although, judging from the position in which the mature worms occurred in the lungs of animals, he feared they could not be reached by inhalations. In reference to the ciliated embryos, it was interesting to notice, that while in *D. Ringeri* it took at least a month to rear the actively swimming larvæ, in *Bilharzia* the rearing could be accomplished in from two to six minutes if the water was slightly warmed. Parasitic lung disease was extremely common in animals from nematode worms, which proved more fatal to their hosts than did the flukes. He congratulated Dr. Manson on the results of his opening investigation.—Dr. S. Mackenzie thanked Dr. Manson for his researches and arduous labor carried on under great difficulties. He thought that cases of endemic hæmoptysis might probably be met with in this country.—The President quite agreed with the author and with Dr. Cobbold on the importance of these parasitic diseases. There were now several forms of flukes found in man. He appreciated the author's remarks about the geographical distribution of this disease, but thought this parasite would be found in other places.—Dr. Manson briefly replied.

Alpine Winter Health Resorts.

A meeting of this Society was held on April 2nd, Sir Joseph Fayrer, President, in the chair.

Dr. Symes Thompson read a paper on Alpine Winter Health resorts. He showed first that the value of Alpine stations in winter was not limited to patients suffering from chest disease; next, that those likely to gain from mountain treatment might safely undertake the journey even in mid-winter; and that for overworked professional men needing a change a winter trip to the Engadine was as enjoyable, and often more beneficial, than a summer tour. The number of cloudless (average 64) and windless (average 112) days is the marked feature of the climate. After taking a survey of other meteorological questions, many of which are undetermined, he pointed out the classes of cases most suitable for the mountains. A patient ought to be able to keep up his circulation by active exercise, susceptibility to chilblains being a contra-indication, also a tendency to irritable throat, which the dry atmosphere often increases. In chlorosis benefit is not so marked as might be expected, and the air is too exciting for hysterical patients. Those prone to congestion and nervous headaches, rheumatism, neuralgia, and to jaundice and liver affections, are apt to suffer on exposure to cold. Constipation is common, and piles troublesome; chronic skin affections do not improve as a rule. Teeth rapidly deteriorate, and it is important that before going to the Alps patients should visit their dentist. Cases of bronchitis, whether acute, subacute, or chronic, should not be sent, but limited and localized lung consolidations

—the result of pneumonia or pleurisy—are among the more favorable cases, the hardened portions of lung becoming pervious and the surrounding healthy lung expanding. In bronchiectasis gradual improvement may be looked for. Spasmodic asthma is generally relieved in winter, as in summer; more so, indeed, for the weather is more steady and reliable in winter. Cases of bronchial asthma are suitable only when there is residual thickening. Cardiac cases do badly. In phthisis the grounds for selection are based less on the stage and character of the disease than on the constitutional state. The fact that the lung disease is so extensive as to lead to dyspnoea, increased at the high altitude, is no barrier; some of these cases improving greatly. If the disease is of limited area, surrounded by healthy lung, the prospect is favorable, whether signs of consolidation, of softening, or excavation exist. If the local evil is of pneumonic origin the prognosis is good, but if due to inherited tubercular disease, even though bacilli are present in the sputa, at least temporary gain may be looked for. Hemorrhagic cases are most favorable. Hemoptysis is not directly induced by the rarefied air, but the resulting exhilaration tempts to over-exertion. Sanguine, excitable patients need increased vigilance against incautious exertion or exposure, while those of a lymphatic temperament must be urged to overcome their disinclination for out-door exercise. A week or two may do much in cases of mental overstrain, but for chronic lung disease at least one month, and perhaps two or three months, may be needed to secure permanent arrest. During a recent visit to St. Moritz and Davos, Dr. Symes Thompson examined a large number of cases. He noticed most marked improvement in the aspect of the patients, many with advanced disease looking and acting as if well, muscular development improved, chest circumference increased, though not to a large extent. Briefly to epitomize the cases there were: four of mental overstrain, all markedly benefited; two of anæmia, one much better, the other not improved; three of cardiac disease, in one case of aortic regurgitation and one of weak heart with mitral disease, the ill effect of the climate was marked, in one of aortic regurgitation no effect noticed; of five cases of asthma all improved greatly; of the phthisical cases, six in the first stage, five improved, one not benefited; of fourteen cases in the second stage, eleven improved, two stationary, and one died; of fourteen cases in the third stage, nine improved, two stationary, and three have died. He expressed his conviction that it would be hard to find elsewhere a series of cases of arrested phthisis comparable to those seen at Davos and St. Moritz in January last.—Dr. C. T. Williams had been originally opposed to this treatment of lung disease, but had come to see its value, which had been so much insisted on by Dr. H. Weber. He would like to know the ground for Dr. Thompson's assertion that the dryness of the air at Davos and St. Moritz was greater than at Egypt. The feature of Davos is the great heat of the sun, and the intense cold in the shade and night. Caution was necessary in having windows open at night, as the temperature may fall to -2° F., and he had seen harm done by the practice. He was confirmed in his opinion that the climate increases the tendency to pyrexia. More suitable cases were sent to Davos now than formerly. Patients gained weight, appetite, vigor, and in power of resisting cold. The effect on the lungs and chest walls from hypertrophy of the healthy lung was most marked; the change is gradual, but it occurs in every case, even in the bedridden, and therefore quite apart from increased muscular development. He found the journey to Davos in

winter to be severe and trying, and the open sledging was a great tax for weakly patients. He advised his patients to go in October, and to move when the snow melts, halting on their way home at Thusis and Berne.—Dr. De H. Hall mentioned that a patient suffering from pleurisy after typhoid fever had spent two winters at Davos, and had improved very much indeed. He came down too rapidly from Davos, and went to the Lakes, thereby retarding his cure. It was a great advantage to be able to get home earlier from Davos than from the Riviera. He asked for information as to the effect of such climate upon cases of fistulous empyema.—Dr. C. Wise had had experience of cold climates in Canada, and had lately spent winters in Davos. His experience was that a sleigh drive of over ten miles on a cold day was too much for delicate people, even ever so well wrapped up. Swiss trains are overheated, but those between Basle and Calais are not sufficiently heated. The ventilation at these high altitudes is imperfect, and he had found it impossible to sleep with his window open at night. The cold at St. Moritz was but little greater than at Davos. Wiesen was less intensely cold. It was well for patients to leave before the snow melts on account of the winds. Natives die from pneumonia attributable to the sudden chills and changes in mode of life. From his observations he had found the absolute amount of moisture in the air was less at high altitudes than in Egypt, and in any of these places than occasionally in Australia.—Dr. Cullimore said the climate was not suitable for asthma or heart affections. Only when lung disease is limited is residence at Davos good, and where hereditary tendency and hectic were absent. Nervous diseases do badly, and it is dangerous for patients with degenerate arteries. He thought that for consumptives mountain resorts were bad, and the rage for sending patients to them would soon pass away.—The President said too much importance had been attached to altitude; it was pure air that is of most value. For many years he resorted to altitudes of 6,000 or 7,000 feet, and did not experience the remarkable effects attributed to altitude. People had gone to 14,000 or 20,000 feet without suffering from such effects. The dryness of the air has the greatest effect. The winds of India are intensely dry, and also those blowing over the Red Sea. In India, hill climates are of immense benefit to many classes of patients.—Dr. Symes Thompson said that the difference between day and night temperature was small. Cases of hypochondriasis and brain disease do not improve; they are troubled with sleeplessness. The electrical condition of the air is very remarkable. Asthma is very much benefited at Davos.

PATHOLOGICAL SOCIETY OF LONDON.

Cancer of Stomach and Subcutaneous Tissue.—Lymphatic Cyst.—Tumour of Skull and Bladder.—Rheumatic Nodules.—Acute Gastritis.—Diffuse Lipoma.—Acute Yellow Atrophy of the Liver.—Vesical Calculus.

THE ordinary meeting of this Society was held on March 20th, Mr. J. W. Hulke, F.R.S., President, in the chair.

Dr. Coupland read the report of the Morbid Growths Committee on Dr. Sharkey's specimen of Syphilitic Disease of the Capsule of the Liver, in which Dr. Sharkey's description was confirmed.

Dr. Finlay showed specimens from a case of Epithelioma of Stomach with widely diffused Secondary Growths. The patient from whom the

specimen was obtained was admitted into the Middlesex Hospital, under the care of Dr. Cayley, on Sept. 24th, 1882. Six weeks before admission he had complained of aching pains in the back and epigastrium, and about the same time a small swelling appeared to the right of the umbilicus. This gradually increased in size and became tender, and was soon followed by the appearance of other similar tumours, varying in size from a pea to a horse-chestnut, on various parts of the body. He had had occasional hæmorrhage from the bowels, and was habitually constipated. He had never vomited blood, but had recently suffered from occasional attacks of retching. He was anæmic and emaciated, but with the exception of the subcutaneous nodules nothing abnormal could be detected about him; in particular no evidence of any internal tumour was obtained. One of the nodules, cut out during life, was found on microscopic examination to consist of alveoli, lined with cells resembling columnar epithelium. The patient died after being about five weeks in the hospital, the nodules having increased in number and size. A week before death he had vomited all his food, but this was never a prominent feature of the case. The post-mortem examination, which was made by Dr. Fowler, thirty-seven hours after death, revealed a growth in the posterior wall of the stomach, occupying an area of about $3\frac{1}{2}$ in. by 3 in. and extending downwards from the point of entrance of the œsophagus. There were widely spread secondary deposits in the mesentery, diaphragm, retro-peritoneal and bronchial glands, liver, right lung, and left suprarenal capsule, as well as in the subcutaneous tissues. Under the microscope the new growth was found to present in all the different parts a structure consisting chiefly of oval, circular, or horseshoe-shaped alveoli, lined with cylindrical epithelium, imbedded in a stroma of fibrous tissue. The type of columnar cells was most distinct in the growth in the stomach, the fibrous tissue most abundant in the subcutaneous nodules. The stomach was held to be the primary seat of the disease, and the blood to have been the agent in the dissemination of the cancerous infection to the remoter structures.—Mr. Hulke never remembered any instance of such a number of secondary epithelial nodules as in this case; and it was quite remarkable to find these nodules in a tissue so far removed from epithelial tissue in its nature as is subcutaneous tissue.—Dr. Conpland referred to a case of cancer of the sigmoid flexure with a secondary nodule at the umbilicus. From the structure of the nodule excised during life, Dr. Cayley surmised that the primary growth was in the alimentary canal; this greatly added to the practical interest of Dr. Finlay's case.

Mr. A. E. Barker showed a Lymphatic Cyst. A child was in the University College Hospital under Mr. Marshall, suffering from what was diagnosed as nævoid lipoma of the thigh. The thigh was amputated at the hip-joint, and the child died in a few hours. At the autopsy a small cyst with a thin wall was found in contact with the wall of the bladder, the surface irregular, contents thin and serous; another, much larger, was found below the right kidney, just beneath the peritoneum. The sac was loculated with smooth lining. Another was found in the scrotum, extending beneath the penis, from right to left. All three cysts were in one line. Mr. Barker tried to inject blue fluid into them from the lymphatics of the testicle, and from the bladder, but failed. He considered them all to be dilated lymphatic spaces. The cysts were on the same side as the nævoid growth of the vessels.

Mr. Barker showed a specimen of Prolapse of

the Uterus, causing obstruction to the ureters. The bladder was drawn down with the uterus and lay between the thighs. The ureters and pelvis of kidney on both sides were dilated; there were signs of old interstitial nephritis in the form of punctate depressions on the surface of the kidney. There was no trace of inflammation spreading up from the kidney, but the changes seemed to be all due simply and solely to the obstruction of flow of urine into the bladder.

Mr. Clutton showed specimens from a case of Tumour of the Skull and the Bladder in a man aged sixty-two, who was first seen in September, 1877, with a swelling over and fixed to the left parietal bone, soft in the centre, with an infiltrating indurated margin. This was opened in October, and a large aperture in the skull was then found. He died in May, 1878, sinking under the profuse discharge from this ulcer and hectic. He suffered severely from neuralgia, but had no paralytic symptoms, nor any bladder symptoms. At the autopsy a hole three inches across was found in the skull, and an ulcer in the scalp, five by four inches. The skin around was infiltrated with new growth, and the margin of bone was spongy and in part dead. The exposed dura mater was thick and rough, and in its centre was an aperture the size of a florin, and beneath this the brain showed signs of commencing hernia. A tumour the size of an orange was found to occupy the left side of the body of the bladder, both inside and outside; its margin well defined. No other new growths were found. Microscopic examination of the tumour of the head showed in the main an alveolar structure, large and small groups of large cells, with distinct nuclei and nucleoli, with interalveolar small round and spindle cells. In places the large cells were scattered irregularly, in others bundles of spindle-cells were seen. This Mr. Clutton considered to be an alveolar sarcoma. The bladder tumour was of quite different structure, composed of round and oval cells like those found in sarcoma. In places there was a faint indication of an alveolar network, but the cells were not grouped together, nor in any other way did they resemble the large cells of the other tumour. Mr. Clutton said that the difference in the structure of the two tumours rendered the interpretation of the case difficult, but he thought it possible that the bladder tumour was a secondary development of that on the head.—Mr. Butlin thought that the skull tumour was an ordinary epithelium of the skull, and he believed that in the bladder was the primary growth. He hoped the case would be referred to the Morbid Growths Committee.—Dr. Thin suggested that the nodules in the skin should be examined, as there had been several cases of tumours springing from the deeper parts of the skin, depressing the bone and growing into the diploë. He thought the skull tumour was like rodent ulcer.—Mr. Roger Williams suggested that the two tumours were independent. The naked-eye characters of the bladder tumour were not those of epithelioma. Bladder tumours might not produce any symptoms unless they interfere with the ureter or the urethra, or were ulcerated. He thought the tumour in the bladder was a round-celled sarcoma.—Mr. Hulke said that tumours of the head might perforate the skull without producing any symptoms.—Mr. Clutton had carefully examined many sections of the specimen, and upon that he came to the conclusion that it was a sarcoma.

Dr. Angel Money showed microscopic sections of a Rheumatic Subcutaneous Nodule. The patient was a female, aged ten years, who had had scarlet fever, followed by rheumatism three years previously, from which time cardiac disease proba-

bly dated. She had had frequent attacks of rheumatism and some choreic movements. There was a history of rheumatic fever in the father, and one of chorea in a sister. There were signs of great hypertrophy of the heart; the rheumatic nodules had been noted by the patient for some time, possibly months; they were found in the right and left elbows and on the right patella. The clinical history was of a fluctuating sort, dyspnoea and oedema coming and going without much apparent reason; the patient died rather unexpectedly. At the autopsy the heart was found to be enlarged and dilated, the pericardium universally but not firmly adherent. Some nodules about the size of a millet seed were to be felt in the wall of the right ventricle. There were some slight valvular changes. The liver, spleen, and kidneys showed some of the usual changes, probably secondary to the cardiac mischief. Sections from a nodule on the back of the right elbow were interpreted to consist of fibro-cartilaginous tissue. A section of a nodule from the pericardium looked something like connective tissue from a tendon of a mouse's tail. There were the signs of a chronic diffuse peri and myo-carditis.

Dr. Cavafy showed a heart and some casts, and microscopic specimens of Rheumatic Nodules. The patient was a boy aged seventeen, who had suffered once from acute rheumatism, ever since which he had dyspnoea and palpitation, and he died from heart disease. The rheumatic nodules—sixteen in all—were found over hands, elbows, and patella. They were symmetrical and varied in size from half a pea to a hazel nut, skin over them healthy; they only ached occasionally and slightly; they were not tender. They were slightly movable over the bones, and freely so under the skin. The smaller ones were harder and firmer than the larger. There was found post mortem advanced heart disease, with mitral obstruction and regurgitation, and great dilatation and hypertrophy. A ring of minute rough vegetations was found on the auricular side of the mitral valve. The aortic valves were similarly diseased. Two nodules from the elbow were examined, they appeared to be attached to the triceps. A small one consisted of young actively growing fibrous tissue cells, and much intercellular tissue. A larger one had a much looser texture, though consisting undoubtedly of fibrous tissue; strands of fibres were separated widely by oedema and a cellular infiltration. Numerous curious figures were also seen, giving a fenestrated appearance; the meshes were square in shape, ladder-like; he thought that there was an infiltration of fibrine which coagulated and gave this appearance, for material in the blood-vessels and in these meshes stained in the same way. Both nodules were very vascular, and the small arteries were enormously thickened in the inner coat, so as to obliterate the lumen of some of the vessels. In the larger nodule thickened arteries were also seen, but most of the vessels showed only proliferation of the endothelium.

Dr. DREWETT showed a boy, aged seven, with Rheumatic Nodules; the nodules had recently come out. These nodules occurred most generally over subcutaneous bones where they are most exposed to pressure and friction from clothes, and in this he thought they were homologous in origin to valvular vegetations. These nodules apparently always accompanied heart disease. He thought they were important in diagnosis, prognosis, and treatment.—Dr. Payne drew attention to the fact that very similar nodules to these are found in chronic rheumatoid arthritis; he had often met with them, and had seen them disappear. Last year he had a woman with chronic rheumatoid arthritis, who, two years before, had

shown these nodules, but when last seen they had quite disappeared. He had seen them in cases of symmetrical enlargement and stiffness of the wrist, elbow, and radio-ulnar joints. He asked whether these nodules occurred otherwise than in the neighborhood of chronically diseased joints, and whether they were not the result of changes similar to those going on inside the joint?—Mr. Parker had examined nodules from four cases of this disease. None of them were so highly organized as Dr. Cavafy's. In one of Dr. Barlow's cases the vessels were not thickened so much. In all of his cases the nodules consisted of very vascular, coarse, white, fibrous tissue. The nodules developed and disappeared suddenly and involved the tissue specially affected by rheumatism. His last case was in a girl, aged eleven, with severe chorea, and a nodule developed on the tip of each spinous process just when her choreic symptoms became notably worse, and he asked whether this was to be considered as a relapse of rheumatism.—Dr. Stephen Mackenzie remarked that similar changes of the intima were seen in other inflammatory affections of bloodvessels, as in pyæmia and scarlet fever.—Dr. Mahomed asked if the skin ever inflamed over these nodules. He had a patient who had many large nodules, and several of them were covered with red skin; some of them were softened—indeed, they looked like gummata. In a man with severe osteo-arthritis there were many nodules, but they were larger than those he had seen in children with a history of rheumatism.—Mr. Eve referred to a case of xanthelasma nodosum, brought forward by Dr. Gilbert Smith, in which the structure was like that of these nodules.—Mr. Hutchinson had several times seen these nodules inflamed, at least in chronic rheumatic arthritis, and some in cases of gout.

Mr. Herbert Page showed a Stomach after Gastrostomy performed last month. The stomach was opened on the fifth day; no bad symptom came on till the twenty-second day, when the patient had a violent attack of vomiting; fever came on, and the patient died in collapse next morning. There was a parenchymatous inflammation of the stomach, which, he thought, was started by the wound in the stomach walls.—Mr. Silcock, who made the autopsy, said that the coats of the stomach were generally thickened, most so at the fundus. It was of a dead-white color, with effusion under the peritoneum. On section milky fluid exuded. The rugæ were quite obliterated. In the peritoneum was a quantity of buttery lymph, but no plastic lymph. Thirty-one cases of this disease had been collected; the majority had arisen in acute fevers; others in cases of acute alcoholic poisoning; some had arisen from injury to the stomach. He suggested that in this case it originated from digestion of the margin of the mucous membrane at the opening in the stomach. The fluid in the stomach was crammed with micrococci.

Mr. Hutchinson showed a Fatty Tumour of the Neck of a man. Large masses developed quite symmetrically in the neck. The case was exactly like that recorded by Mr. Morratt Baker. Symmetrical masses of fat also were present under the jaw, and in both forearms. He had also symmetrical hypertrophy of the parotid gland, and tumours of the parotid. On cutting down on to the neck he found the mass was not encapsuled, but adherent to the skin; it was, indeed, hypertrophy of the subcutaneous fat. The mass removed consisted of very firm fat. He also showed two photographs of a man with a similar affection of the parotid gland and proptosis.

Dr. Cayley showed a specimen of Acute Yellow Atrophy of the Liver with clear limitation of the atrophied part. The atrophied portion showed no

liver tissue at all. The symptoms were those common in acute yellow atrophy.

Mr. George Lawson exhibited a Stone which he had removed from a man aged forty-eight at the Middlesex Hospital by lithotomy on March 10th. When the patient was examined, the stone was felt to be very hard and large, and Mr. Lawson thought that lithotomy afforded a better prospect of success than a Bigelow's operation. When removed, the stone was found to measure two inches and a half in length, two inches in width, and one inch and a half in depth. It weighed four ounces all but sixty grains. Its surface was nearly smooth, of a yellowish-white color, and when washed was inodorous. On making a section of the stone about a drachm of a reddish-brown stinking ammoniacal fluid escaped. The nucleus of the stone was a mulberry calculus, very rugged in outline and measuring seven-eighths of an inch in each of its two principal diameters. The bed in which this calculus lay was too large for it, so that there was a free space around it, and this space was filled up with the reddish-brown fluid. Mr. Lawson thought that the explanation of the manner in which this collection of ammoniacal fluid was incarcerated within the stone was the following:—At the period of the stone's growth, when the mulberry calculus was free in the bladder, there had been cystitis, and the interstices between the nodules had become filled up with mucus, and mucus mingled with ammoniacal urine. The irregularities of the stone being thus obliterated, it presented a tolerably smooth surface, upon which the salts of the urine were deposited in concentric laminae, as seen in the specimen. A quantity of ammoniacal and tenacious matter was thus pent-up within the stone, and this undergoing decomposition and becoming stained with the color of the oxalate of lime calculus with which it was in contact, produced the reddish-brown ammoniacal fluid which escaped when the section of the stone was made. The patient had done well.

Discussion on Diabetes.

The ordinary meeting of the above Society was held on April 3rd, Mr. J. W. Hulke, F.R.S., President, in the chair. The discussion on diabetes was opened by Dr. S. Wilks, and joined in by Dr. Ralfe, Dr. Finlay, Dr. Hale White, and Dr. Stephen Mackenzie. To a large extent their speeches were negative rather than positive, and the only theory advanced was one by Dr. Ralfe, that diabetic coma is caused by the production of aceto-acetic acid in the blood. The honorary secretary showed for Dr. Hamilton an excellent specimen of lipæmia. The discussion was adjourned till May 1st.

Mr. Hulke prefaced the discussion by remarking that although certain morbid changes had been observed in cases of diabetes, he did not know whether these were peculiar to diabetes, and if so, how far they were causal. He hoped that the discussion would be limited to diabetes mellitus, and that cases of polyuria, and of that form of saccharine diabetes which occurred in elderly persons, and lasted oftentimes for years without producing any ill effects, would not be considered along with the cases of the severe and acute form of the disease.—Dr. S. Wilks had no new facts to advance, but yet he considered that this subject was one well suited for discussion. He thought that all the anatomical changes found in diabetes were results of some ulterior factor, but it was the part of this Society to record all such anatomical facts. He well remembered Dr. Bernard's original experiments on the artificial production of glycosuria; but so far as his own experience went, he had not found any changes in the fourth ventricle in pa-

tients who had died from diabetes. He referred also to Dr. Ogle's statements in reference to the spinal cord, and suggested that some facts in relation to the sympathetic centres might be discovered if carefully sought for. Also, he was interested to know how the liver was changed. Whether it was enlarged merely or altered in structure in any way. The pancreas, too, had been stated to be affected; the stomach and kidneys also deserved notice. The kidneys had an increased function thrown upon them, and it was interesting to know whether this was always attended with true hypertrophy. The skin had been said to be altered. He remembered seeing a patient bled, and the whole surface of the blood was covered with fat; and this point had recently come up afresh. His impression was very strong that twenty years ago he should have said that diabetic patients died from phthisis; whereas now he would say they died from coma, and it would be interesting to know whether there was any change in this matter and what the facts really were. He asked, too, whether, when diabetics died from lung disease, that disease was special in its nature or ordinary tubercular phthisis.—Dr. Ralfe said he would limit his remarks to the question of acetonæmia. He distinguished between two forms of diabetic coma, to the latter, by far the rarer of the two, he thought the term acetonæmia should alone be applied. He regarded it, however, purely as an accident in the course of the disease, and not at all as a natural sequence. After describing the characteristic symptoms of this condition, he drew a parallel between acute diabetic coma or acetonæmia and those of acute yellow atrophy and phosphorus poisoning. The sudden, sharp epigastric pain, accompanied with gastric disturbance, often with vomiting, the vomit sometimes containing blood; the peculiar dyspnoea, which had been likened to the panting of an animal in which both vagi had been cut; the stage of short, noisy delirium followed almost suddenly by deep coma; the fall in temperature as the nervous symptoms developed; the irregular pulse finally becoming intensely rapid as the coma deepened—are all symptoms common to acetonæmia and to acute yellow atrophy and phosphorus poisoning. He doubted whether acetone was ever found free in the blood, though there was no doubt of its existence in diabetic urine. He believed, however, that the blood contained some body that yielded acetone readily on decomposition. This body some had supposed was ethyl-diacetate, but more recent investigations had shown that it was probably aceto-acetic acid. If this was ultimately proved, then we might offer an explanation (1) of the highly acid condition of urine so frequently associated with diabetes; (2) the lactescens condition of blood, since acetic acid will give a milky appearance when agitated with a dilute and slightly alkaline mixture of fatty matter at 100° F.; (3) the intense fatty degeneration so noticeable in cases of acute diabetic coma; since it was well known that the injection of acids into the blood of animals leads to increase of the fatty matter in the blood, and of fatty infiltration in the tissues and organs. Dr. Ralfe here again pointed out the parallelism between acetonæmia and acute yellow atrophy and phosphorus poisoning, and alluded to a case quoted by Professor Gamgee of acute diabetic coma with lipæmic condition of blood, in which the liver was the seat of intense fatty infiltration similar to that observed in cases of poisoning by phosphorus. He thought there was no ground for doubting the presence of aceto-acetic acid—given glucose in the blood—since it was one of the many products of alcoholic fermentation. In conclusion, he thought we might be warranted in regarding this acute form of diabetic coma as due to a

toxic agent; that this agent was of an acid nature; that it was formed from the alcoholic fermentation of the glucose in the blood; that in small quantities it was present in all cases of diabetes, giving to the urine the highly acid reaction so characteristic of the disease; that occasionally and on rare occasions it is sometimes formed to an excessive extent, or its excretion is interfered with, in which case it gives rise to symptoms closely parallel with those observed in acute yellow atrophy, etc. Dr. Ralfe thought that if it could be shown that acute diabetic coma depended on a toxic condition, and was not due to any sudden nervous lesion, then the treatment should be directed towards altering the percentage composition of the blood with relation to the toxic agent, which he thought would be best effected by transfusion, either with blood, or even simple water, or a dilute saline solution, whilst endeavors should be made to rouse the patient and promote full action of the skin, which he thought could be attained by use of the cold pack, etc. Dr. Ralfe then demonstrated the presence of acetone in diabetic urine with ferric chloride and with the iodoform reactions, and described briefly how acetone could be quantitatively estimated in a given quantity of urine.

Dr. Finlay showed microscopic sections of lung, kidney, liver, brain, and spinal cord from a case of diabetes which he had had under his care a few months ago in the Middlesex Hospital. The patient died comatose on the second day after admission. The history of diabetes was of only a month's duration; the urine contained 5 per cent. of sugar. On the morning of the second day after admission he complained of difficulty of breathing, and became restless and somewhat delirious. When seen at 2 P.M. his breathing was labored and stridulous; and he was in a semi-unconscious state with a dry and brown tongue, but no sour smell in the breath. Percussion resonance over the chest was normal, and the breath sounds merely harsh. He sank into a comatose condition, and died at 7.15 P.M., about ten hours after the graver symptoms set in. At the post-mortem examination, which was made by Dr. Fowler, the muscles were found to be of a dark-red color, the mesenteric glands slightly enlarged, the lungs engorged and friable, and the pancreas the seat of a small hæmorrhage. The liver appeared normal, weighing 52½ ounces; the spleen was small and pale, and the kidneys were normal with the exception of slightly adherent capsules. The pia mater was injected; the brain substance was firm, and appeared in every respect normal to the naked eye, as were also the cord and its membranes. The blood shaken up with ether yielded no fat, and microscopically examined appeared perfectly normal. With regard to the specimens shown, taking the organs in order, the lung tissue was seen to be normal, in particular no fat embolisms being present. Although there were a few rounded bodies which stained black with osmic acid, these were in the alveoli, not in the vessels, and were probably fattily degenerated epithelium cells. The kidney showed granular degeneration of the secreting epithelium and some hyaline casts in the tubules. The liver cells were granular and ill defined. No dilatation of capillaries was observed. As to the nervous centres, sections from the pons and medulla showed to some extent the eribriform appearance described by Dr. Dickinson, but the excavations were small, and not common to all the arteries. Some of these were taken to be the result of the manipulation of the sections in cutting and mounting; and as to the rest, it might fairly be questioned whether they were not more likely to be the consequence than the cause of the disease. There was nothing noteworthy in the con-

dition of the cord, the central canal appearing natural. In the record of the case there seemed nothing to suggest an essential pathology, and he thought it would be unsafe to do so until we had a much larger store of post-mortem records, with microscopic examinations of all the viscera, which might be concerned in the causation of the disease. His colleague, Dr. Coupland, and himself had searched the post-mortem records of the Middlesex Hospital over a period of thirty-two years, and had found particulars of twenty cases of diabetes, of which a tabular statement and summary were given. In the course of this reference was made to the interesting fact that a well-marked case of lipæmia was observed in 1859 by the late Dr. C. Coote, Assistant-Physician to the Middlesex Hospital, who made it the basis of an elaborate paper, reviewing the whole subject, in *THE LANCET*, in 1860.—Dr. Hale White criticised in detail that theory for the pathology of diabetes which refers it to the existence of vacuolation in the nervous centres. In the first place, he showed that out of twenty-three post-mortem examinations at Guy's on diabetic subjects no changes in the nervous centres were detected. He exhibited microscopical sections of the nervous centres from some of them, together with the entire brain, in which it was evident that the only appearance that could in any way be called vacuolation was due to the falling out of vessels from their spaces. Sections of a healthy brain showing this false vacuolation were shown. Specimens of the true vacuolated, or "Gruyère cheese," condition, were brought forward, and in all of them it was pointed out that in the subjects from which they were taken there was no sugar in the urine; for these two reasons it was inferred that the pathology of diabetes was not to be found in any such condition of brain, which, if it did cause diabetes, would surely sometimes affect other centres, such as those of the seventh or ninth nerves, an unknown complication of diabetes. Dr. Hale White next treated of the relation of glycosuria to insanity, and gave full tables of the condition of the urine in 124 cases of insanity which he tested at Bethlem with Dr. Savage, and at the Surrey County Asylum with Dr. Paddison, and out of these only 2.56 per cent. contained sugar. This statement was contrasted with that of Dr. Dickinson, who gave the percentage at 16.65, and it was suggested that probably this difference was due to the fact that the latter had mistaken some cases in which there was abundant uric acid for glycosuric ones. Finally, it was shown that it was not a fact, as has been stated, that children with tubercle are liable to glycosuria. For these reasons Dr. White was not disposed to agree with any theory that had been put forward to connect the disease with described morbid conditions of brain.

Dr. Stephen Mackenzie divided his remarks into three divisions:—(1) An analysis of a number of fatal cases; (2) the naked-eye appearances in the body after death; and, (3) the microscopic appearances in the cases examined. 1. The fatal cases in the London Hospital during eight years and a half numbered thirty-seven. Of these, nineteen were due to coma; in seven of which no disease was found after death; in three there were no signs of pulmonary or other visceral changes during life; in one pulmonary disease existed during life; in four there were signs of recent pneumonia or phthisis; and in four old pneumonia or phthisis existed (in the twelve last-mentioned cases no necropsy was made). The remaining eighteen cases were as follows:—There was cerebral hæmorrhage in one; cerebral meningitis, coma, in one; cerebral tumour in one; spinal cord disease and phthisis in one; stricture of urethra, suppurative nephritis,

and coma in one; scrofulous nephritis and phthisis in one; pneumonic phthisis in nine; scirrhus of pancreas, sudden collapse, in one; gangrene of foot, death rather sudden, in one; dermoid ovarian cyst, calcified mesenteric glands (supposed to have helped herself to codela), in one. Some remarks were then made as to the changes found in relation to cause or effect. In twenty out of thirty-seven cases there were pneumonic or phthisical changes. It was pointed out that the phthisical changes were found in two organs only, the lungs and the kidneys, organs which were placed under peculiar circumstances in this disease. The occurrence of coma in association with diabetes was next discussed, it being pointed out that it was the determining cause of death in nineteen of thirty-seven cases, excluding all cases in which an explanation, other than diabetes, would account for its occurrence. It was pointed out that the coma in the cases in which pulmonary disease was present differed in no essential way from that in pure cases. As regards its production, the various assigned causes were reviewed. In three cases of pure coma, five of coma with pulmonary disease, and ten miscellaneous cases of diabetes, examination of sections stained with osmic acid showed no fat embolisms, and no fat in the bloodvessels. The pink or laky character of the blood described by some observers was not noticed in these cases, the blood being either natural in appearance or dark, sometimes thick, sometimes fluid. An acetone odor during life, or after death, had not been observed in any of the cases. He therefore concluded that whilst fat embolisms and acetonæmia might account for the coma in some cases, they were too inconstant to serve for a general explanation. At the same time, he thought that its sudden onset, peculiar features, and absence of characteristic lesion after death, pointed to some poison developing in the body; if not acetone, possibly something of an allied nature. 2. Naked-eye appearances: He knew of none pathognomonic, but some were frequent. He had not seen the cribriform condition of the nervous centres described by Dr. Dickinson. The most frequent, besides the emaciation and phthisis, was a slimy homogeneous condition of the liver and spleen. The kidneys were usually large and often congested. The pancreas had only been found diseased in two cases: once scirrhus, once cretaceous. 3. Microscopic appearances: In fourteen cases, in which the nervous system was examined, no changes were found. In six cases slight peri-vascular and periganglionic dilatations were found, but in none to the degree described by Dr. Dickinson. He was doubtful how far they were due to a mode of preservation. Hyaline degeneration of some of the vessels was present in some cases, and miliary aneurisms of the retina in one. In the lungs the changes were chiefly of a necrotic pneumonia. In one case only giant cells were found. Four cases had been examined for bacilli, but none were found in any of these. In six cases intra-alveolar hæmorrhagic extravasations were found; these were all cases of coma, and their occurrence was no doubt due to this cause. In the kidneys the most remarkable changes were a hyaline degeneration of the intima of the small arteries, and a peculiar skeleton-like condition of the epithelium of the collecting tubes. In the spleen a hyaline degeneration of the arteries was found in all the cases (five) examined. The liver showed signs of fatty degeneration in only one of eleven examined, a point of importance in connection with fatty embolism. In the other cases there was atrophy of the liver cells. The pancreas was examined in four cases, but nothing of importance was found. The heart showed signs of wasting and degenera-

(5)

tion. The morbid anatomy of these cases, therefore, was of a barren character, throwing no light on the pathology of diabetes. The changes found must be regarded rather as the consequence of diabetes than as explaining its occurrence.

Microscopic specimens of organs of patients dying with Diabetes were shown by Dr. Finlay, Dr. Stephen Mackenzie, Dr. Seymour Taylor, Dr. Hale White, and Mr. Victor Horsley.

CLINICAL SOCIETY OF LONDON.

Traumatic Gangrene.—Tetanus.

THE ordinary meeting of the Clinical Society was held on March 30th, Dr. Andrew Clark, President, in the chair. The subjects raised by the papers were traumatic gangrene and tetanus. Several cases bearing upon the pathology of tetanus were related.

Mr. Howard Marsh read the Report of the Subcommittee appointed to report on Mr. Shuter's case of Sub-periosteal Amputation of the Hip-joint. The Committee had not evidence enough to enable them to state that there was any new formation of bone in the stump. There was, however, independent movement in the stump itself. The method employed was of advantage from (1) avoidance of hæmorrhage, and (2) the firm attachment of muscles to the periosteum.

Mr. R. W. Parker read a case of Contused Wound of the Thigh and Leg in a Child; Gangrene of Limb; Death. A female child, aged fourteen months, was admitted into the East London Hospital for Children having sustained an extensive wound of the left leg twenty-four hours previously. The wheel of a heavy dray had caught the outer border of the limb and torn off a large crescentic flap of integument; the front of the knee-joint was exposed but not opened. An attempt was made to clear off the mud, with which it was plentifully covered, and so establish an aseptic condition, after which antiseptic dressings were applied. The child appeared to be doing well for about thirty-six hours, after which she became drowsy and restless, and some livid patches and oedema appeared on the foot. Twenty-four hours later these symptoms had become more pronounced, and on the following morning extensive gangrene of the limb had supervened. She died. The author sought the opinion of the members of the Society (1) on the treatment he had adopted and (2) as to the cause of the gangrene. He felt that amputation in the upper third of the thigh, the only alternative, was a severe operation for such an infant; while the suppuration and granulation of such a wound, unless they ran an aseptic course, would almost certainly have proved fatal. As regards the gangrene, no injury to the vessels could be discovered as a cause. Could the action of the carbolic acid have produced such a result?—Mr. Herbert Page referred to a similar case under his own care. A child eighteen months old, caught his arm in a gate. The limb was cold, and next day it was obviously dead to above the elbow, with acute inflammation running up the arm. The child was very ill. Mr. Page at once amputated at the shoulder-joint, and the child quickly recovered. There was fracture of the humerus and olecranon. The brachial artery was plugged in two places opposite a rupture of the two inner coats just above the elbow. He thought that amputation was the proper course, for there was acute inflammation spreading from the gangrenous part. It was advisable not to wait for a line of demarcation. In dry gangrene in old people such a line of demarcation might be waited for.—Mr. Cripps agreed that

it was impossible to lay down a hard-and-fast line as to the proper treatment of cases of traumatic gangrene. In some cases in which the blood-supply was entirely cut off amputation might be postponed; others were cases of spreading gangrene, of which he detailed two examples. One was that of a man with fracture of the arm and wound of the leg, and with dyspnoea. Next day the fingers were blue and swollen. This condition spread up to the elbow. The constitutional state became very grave; the pulse was small and rapid. The arm was amputated at the shoulder-joint, and the vein was seen to be occluded with a clot. Next day the leg began to show signs of gangrene in the foot, then in the leg and thigh, and the man died. At the autopsy the femoral artery was found pervious, and the vein was filled with a clot. The heart was fatty; old pleuritic and pericardial adhesions and fracture of seven ribs were also found; his circulation was feeble before the accident, and then that came to add to the difficulty of the circulation, and so caused stasis and gangrene. In such a case amputation would not have been of any use. The other case was that of a man who injured his hand. Three or four days later the hand swelled very much, and became very painful; the whole forearm was swollen; the fingers were black, the back of the hand bright red, and the pain was extreme. Temperature 104° . After twenty-four hours the arm was amputated at the shoulder-joint, and immediately there was most marked relief. At the end of the fourth day, however, he had a severe rigor, and in forty-eight hours he died of gangrene spreading from the stump. In such a case the gangrene was due to some very acute local pyemic condition, and life might be spared by very early amputation high above the part affected. Mr. C. Heath thought that Mr. Parker acted rightly in not amputating the thigh in his patient. The gangrene was the result of the original injury, not the spreading form. He thought harm was done by lowering the temperature of patients already weakened by playing the spray upon them for some long time. Recently he amputated at the hip-joint the limb of a young girl; she died in twenty-four hours, and he thought that her death was largely due to the amount of carbolic acid absorbed. Her kidneys ceased to act, and did not throw off the carbolic acid by the urine. He thought that an oily dressing to keep up the temperature of the part would have done better for Mr. Parker's patient.—Mr. Parker said that the wound seemed to be so superficial that he was surprised that gangrene ensued. His case was not quite parallel to Mr. Page's. He most feared long septic inflammation, and that was why he used the spray and other aseptic precautions.

Mr. W. Spencer Watson reported a case of Tetanus. A well-nourished boy, aged eight, came under treatment eleven days after receiving a small lacerated wound on the dorsum of the foot. Four days before admission symptoms of tetanus commenced, and on admission the convulsions occurred about once every half hour. At first the temperature was 101° , but afterwards was very little above the normal, being 99.4° ; but the pulse and respiration were much accelerated. The temperature on the second day was 100.2° , and continued at that height till the fourth day, when it went up to 103.2° . He died the same evening. He was treated by the administration of chloral, with occasional morphia injections and rather free purgation. A mustard plaster was applied to the spine. During the third day a severe spasm terminated by sudden cessation of breathing, but artificial respiration succeeded in restoring him. He died in a similar spasm ten hours afterwards. The post mortem

examination showed that the membranes of the brain and cord were intensely congested, but the substance of both appeared healthy. Microscopic sections of the cord gave chiefly negative results. The only appearances that seemed abnormal were the presence of slight vacuities in the grey matter surrounding the vessels and the multipolar cells. It was thought, however, that these spaces were due to the method of preparation of the sections. There was no exudation either in the spaces or in any part of the cord examined, except in some sections of the dorsal region, which presented colloid bodies here and there, such as those described by Dr. Ross. Sections of the peroneal nerve exhibited changes, probably due to inflammation, chiefly affecting the sheath and neuroglia. The questions raised by the case were:—1. Would the performance of neurotomy or amputation at an early stage of the case have given the patient a better chance of recovery? 2. Was the treatment by chloral and morphia the best adapted to the circumstances of the case? 3. Was the case an argument of any value as showing that the microscopic appearances of the cord are sufficient to demonstrate the essential tetanic condition? or are we justified in assuming that at present the microscope fails to give any reliable information?

Mr. Howard Marsh read a paper on a case of Tetanus following laceration of the toes, and lasting forty-two days; Syme's amputation; recovery. Alfred M—, aged eight, was knocked down on September 9th by a tramcar, which passed over his left foot, severely crushing the three inner toes. On September 12th he came into St. Bartholomew's Hospital with the toes gangrenous. On September 23rd tetanus set in, and in the next twenty-four hours rapidly increased in severity, and was attended by frequent and urgent spasms. Syme's amputation was performed in the afternoon of the 24th with the effect that the spasms were both less frequent and less violent. Tetanus, however, continued severe for the next thirty-five days, and then gradually subsided, to cease entirely on the forty-second day. The wound healed slowly, but without complication. It was all but closed at the end of a month after the amputation. Treatment consisted in the administration of an abundant fluid diet, the frequent use of nutritive enemata, and the employment of enemata of chloral and bromide of potassium, and of the hypodermic injection of morphia. The chloral and bromide injections did little, if any, good. But morphia always relieved the spasms and procured rest, though only for short periods. On many days upwards of two grains were injected, as much as five-twelfths being injected at a time. The author remarked that the case was rare not only as an instance of recovery from severe traumatic tetanus, but also on account of the prolonged period (forty-two days) over which the disease extended. Though many authorities were opposed to amputation, he resorted to it in this instance because the operation was not a large one, because the foot was already in part gangrenous, and because amputation afforded the surest means of removing peripheral irritation—a principal indication in the treatment of tetanus. He did not resort to nerve division, as this might fail to check irritation, and he did not know which of the several nerves ought to be divided. In the present instance morphia was the only drug that seemed useful, and though employed in such large doses it produced no unfavorable effect.

Mr. Parker showed a preparation of the Posterior Tibial Nerve from a case of Tetanus. The patient had a gunshot wound of one leg; the wound was thought to be superficial; for a while he got on well, but tetanus came on. Mr. Hutch-

inson stretched the great sciatic nerve, but the man died. The posterior tibial nerve and vessels were found glued together with dense inflammatory matter, and four or five shots were found in the sheath of the nerve. He related another case of a pistol shot in the thigh; tetanus came on. The wound was then explored, and a wad with a portion of cloth was found buried in the soft tissues. A third case was a wound of the leg with a pitchfork; the musculo-cutaneous nerve was here found kinked and stretched; this man also died. He also referred to a fourth case of tetanus in a boy wounded just below the tubercle of the tibia where no local lesions could be found after death. He had seen two cases of tetanus neonatorum without any local lesions or bad hygienic surroundings. This form of tetanus had been known to occur epidemically in hot climates and in states of bad hygiene. He showed microscopic sections of the nerve of the first case, in which the nerve fibrils were found to be widely separated by inflammatory material.

Dr. Dickinson remarked that there was much to favor the view of tetanus being a blood disease, as traumatic tetanus generally occurred when there was an open wound, and after a period of incubation. But no doubt the irritation was conveyed by the nerves and exerted its influence through the nervous system. He had often observed coagulation of the nerves of the part, and in all cases there was hyperæmia of the spinal cord, which was the result of the nervous irritation and not the essential part of the disease. In many cases, too, there was pathological extravasation in the cord, especially on the side opposite to the wounded part. Often there were obvious lesions in the cord, amounting even to tearing in the anterior cornua. He had seen by far the best results of treatment from Calabar bean; especially in two cases—one of them traumatic and very severe. The relation of the injection of the drug and the recession of the spasm was most marked. Chloral had been the next most successful remedy in his hands. Neurotomy was generally performed too late; after the irritation had been carried up to the cord.—Mr. Barwell related a case of a gentleman with trismus and opisthotonos, and a good deal of pain in the right leg where there was a little lump, pressing upon which caused spasm of opisthotonos and left pleurosthotonos. He cut down on the lump and removed a long piece of carpet needle, and as he did this the man had another tetanic spasm; after this he had two more slight spasms, and then got quite well. His temperature before the operations was 102°, the pulse being over 120. In this case there was no open wound. Probably the needle had perforated the nerve. It had originally entered the sole of the foot and had travelled up to the leg.—Mr. Butlin thought it was impossible to discuss the value of any method of treatment in all cases of tetanus while the pathology of the disease was unknown. Some cases began with local symptoms, which after a time became general; and then local operations were useful. As an instance of this, he mentioned a case of injury to the lower limb in which the part was drawn up, a weight was put on, then clonic spasms were seen at first in the limb only; and it was not till forty-eight hours later that the spasms spread to the face and other parts, and death ensued. The popliteal nerve was found surrounded by inflammatory effusion; in such a case as that local treatment—stretching or division of the nerve, or amputation—should be performed before the symptoms spread from the part first injured.—Mr. Howard Marsh said that Calabar bean had been often found unavailing, while chloral had been more

generally useful. Cases had recovered very rapidly after amputation, even when tetanus had been well established. Until the pathology of the disease was cleared up we had nothing to do but to go on recording individual cases as they occur, with their treatment.

A case of Osteitis Deformans was shown in the ante-room by Mr. Howard Marsh.

Removal of Pin from Larynx by Internal Operation.—Scarlatiniform Rash in Enteric Fever.—Scoliosis.—Tabetic Arthropathy.

The ordinary meeting of this Society was held on April 13th, Dr. Andrew Clark, President, in the chair. Four papers were read. Mr. Barker showed a man on whom he had performed subperiosteal amputation at the hip-point, and Mr. Clutton showed a case of cure of spina bifida.

Dr. Felix Semon related a case of Removal by Internal Operation of a Pin from the Larynx of a boy, in which it had been impacted thirteen months, and had caused fixation of the left crico-arytenoid articulation. A boy aged thirteen had in his mouth one day in November, 1881, a pin, which slipped headforemost into the larynx. The symptoms were not at first urgent, but subsequently became severe. Free intervals varied with more or less acute inflammatory exacerbations, manifested by pain, inability to swallow solids, spasmodic cough, and finally even attacks of dyspnoea. It had been supposed all the time that the pin had been impacted in the pharynx and gullet, as its point was felt by Mr. Sydney Jones, under whose care the boy was admitted to St. Thomas's Hospital, on the left side of the pharynx, about the level of the cricoid cartilage, on digital exploration; but laryngoscopic examination revealed that it was far by far the greater part of its length impacted in the larynx, and that only its point, having from within perforated the left ary-epiglottic ligament close to the base of the left arytenoid cartilage, appeared in the oesophagus. The laryngoscope further showed that there was considerable thickening of all the tissues in the upper left of the larynx, that the left arytenoid cartilage was apparently ankylosed, and remained with the left vocal cord immovable in the position of phonation during inspiration. Yet there was neither constant dyspnoea nor impairment of voice. Mr. Jones kindly transferred the case to Dr. Semon, who, after preliminary removal of the greatly enlarged tonsils, and after a few days' practice with laryngeal probes, to accustom the patient to the introduction of instruments, succeeded in seizing, under the guidance of the laryngeal mirror, the projected point of the pin with serrated laryngeal forceps and pulling the pin through the tissues. Great force had to be used in the act of extraction, but the operation was almost painless and bloodless. The pin was found to measure an inch and a quarter in length. No reaction followed, and the boy was dismissed cured from St. Thomas's Hospital five days after the operation. When seen again on April 13th, it was ascertained that the mobility of the left half of the larynx had considerably improved. Amongst the points of interest in the case, Dr. Semon mentioned especially (1) the rarity of successful removal of foreign bodies from the larynx by internal operation after so long an impaction and without previous tracheotomy; (2) the corroboration which this case lent to his former statement concerning the actual occurrence of a non-suppurative, adhesive form of laryngeal perichondritis; (3) the mechanical impairment of the function of the crico-arytenoid joint; and (4) the remarkable absence of all subjective signs, respiratory as well

as phonatory, in spite of the complete immobility of the left half of the larynx and its diagnostic importance. The boy and two other patients suffering from ankylosis of the crico-arytenoid articulation were shown to the Society.

Dr. Whipple related the particulars of two cases lately under his care in St. George's Hospital in which an Eruption resembling that of Scarlatina occurred. The first was in a cabman, aged thirty-six, who had been addicted to drink, but who for twelve months previously to his admission had been a teetotaler. The fever symptoms had commenced fourteen days before, but the bowels had been regular and the motions natural. On admission the man complained of sorethroat and headache, and had a bright erythematous eruption on the trunk, legs, and arms. The right tonsil was much swollen. His tongue was thickly coated, his pulse 128, and his temperature nearly 105°. Next day the eruption was more marked on the arms and legs, and had extended to the feet. On the third day after admission the patient became very restless and delirious, and the bowels, which had been up to this date obstinately constipated, were opened freely by a purge. The diarrhoea thus set up, though somewhat moderated towards the last, continued more or less up to the time of the man's death—i.e., four days after his admission. No typhoid eruption was present. At the autopsy extensive ulceration of Peyer's patches was found. The second case was that of a child, aged four, who was received into hospital on Oct. 6th, 1882. He had already suffered from scarlatina, measles, and whooping-cough. Feverish symptoms manifested themselves on the day before his admission, and when he came under observation his temperature was 104.2°, pulse 120. His tongue was red at the tip and edges, and the papillae protruded from a central white coat. On the day after his admission a red eruption was noticed on the child's legs, and he was therefore isolated. Next day the erythema had greatly extended and was very brilliant, the tonsils were red and swollen. The bowels were constipated. On October 10th (four days after admission) the eruption had faded considerably. The bowels remained inactive and a purge of Karlsbad salt was administered, which acted freely. On the 11th the red eruption had disappeared. On the 13th the temperature reached 105°, and the pulse 132: the child was delirious and had fits of screaming. The bowels acted once after castor oil, the motion being partly formed, and of a clay color. On October 17th characteristic spots of enteric fever appeared, but there was not now nor at any time any desquamation. From this date the symptoms were clearly those of enteric fever, and the child died on the nineteenth day after admission. The post-mortem examination revealed extensive ulceration of Peyer's patches and great swelling of the mesenteric glands. Mr. John Harley, in *Med. Chir. Trans.*, vol. lv., gives twenty-eight cases in which scarlatina was accompanied by swelling of Peyer's patches, but in only two of which ulceration was found, and also a second series of six cases in which scarlatina preceded enteric fever, and further narrates three cases of "mixed scarlet and enteric fever." He also quotes two similar cases recorded by M. Forget. Dr. Murchison says that in many cases of enteric fever the characteristic eruption is preceded by a delicate scarlet rash, and adds that "this is not peculiar to enteric fever, but occurs in other forms of pyrexia." Sir W. Jenner, speaking of a red rash in enteric fever, says that the disease was mistaken for scarlatina. Dr. Whipple stated that he had lately seen a case of variola which was preceded by erythema of the abdomen and thighs. The question was, Were these really cases of

double poisoning, of mixed scarlet and enteric fevers? The absence of desquamation and the fact that an erythematous eruption is not uncommon in variola, pyæmia, and other forms of pyrexia, led to the conclusion that they were really instances of enteric fever preceded by erythema, and not mixed cases of scarlatina and enteric fever. The lungs were intensely congested. Death was due entirely to the enteric fever in both cases.

Dr. Mahomed was quite familiar with a roseolous rash in the early stage of typhoid fever. He had seen it several times. A case was brought to the Fever Hospital with a certificate of scarlet fever. She was in the scarlet fever ward from five to six days, and she then had a very severe attack of scarlet fever. While in the ward she had pyrexia and diarrhoea. She died, and at the autopsy she showed all the signs of advanced typhoid fever. Recently he saw cases of the same kind. One was a patient under Dr. Taylor's care in the third week of typhoid fever, with a rash exactly like that of scarlatina. The rash was not followed by a marked desquamation. He thought there were four rashes in typhoid fever, roseola, rose spots, taches blénâtres, and miliaria. He had not seen a similar erythematous rash in any case of typhus fever.

Dr. Cavafy thought the paper raised the question of the occurrence of roseolous rashes quite apart from scarlatina as from drugs, or after slight surgical operations, in the puerperal condition—uterine erythema, and in connection with menstruation. It would be useful to discover some band of connection between all these conditions. This he thought must be some irritation of the nervous system leading to paralysis of the vaso-motor nerves. He asked whether it was possible to diagnose these cases from true scarlatina. He referred to a case taking salicylate of soda who had sore-throat, and a bright punctate rash with circumscribed erythematous patches which became herpetic vesicles; desquamation was very free. Desquamation must not decide the question, for this might occur also in the quinine eruption. He thought the question of diagnosis was at times impossible without further information.—Dr. Andrew Clark said he was sure that the nervous system was operative in causing erythematous eruptions. Thus, in baring the chest of a nervous patient for examination, an erythema frequently occurs, which is often followed by desquamation. He was familiar with erythema occurring in the course of typhoid fever, and always in anomalous cases, in which the nervous system was much affected.—Mr. Broadbent was only familiar with the delicate roseolar rash, described by Murchison as occurring in typhoid fever, which could not be confused with scarlatina. He had no doubt of the concurrence of typhoid fever and scarlatina. He thought Dr. Whipple's second case was one of scarlatina, immediately preceding enteric. He referred to the case of a man with loss of general nerve tone, in whom, whenever he stripped, an intense erythema spread over the whole chest, abdomen, and back, fading in patches, and associated with taches cérébrales and fibrillar contraction.—Dr. Clark added, that some indications of the nervous erythema or doctor's rash may remain for thirty-six hours.—Mr. H. Page said erythema was seen at the onset of acute rheumatism, and at the commencement of variola. He also mentioned a case of intense scarlatiniform rash preceding chicken-pox; and he agreed with Dr. Cavafy in ascribing it to a nervous origin.—Dr. Whipple thought that Dr. Cavafy had raised the chief difficulty in these cases in reference to the question of isolation. He had, perhaps, laid too much stress on the point of desquamation, but it was remarkable that in the

boy there was no desquamation in nineteen days after an intense erythema.

Mr. Bernard Roth showed a case of Lateral Curvature of the Spine, illustrating its Treatment without the Use of Mechanical Supports. The following is a summary of the paper:—(1) The importance of noticing osseous deformity, if any, of the spine and ribs, and whether the patient can be at once restored to the normal position, and if not, to what extent. (2) If even slight osseous deformity be present complete cure is impossible. (3) Even severe cases of lateral curvature often have no osseous deformity, and can be at once temporarily restored to a normal position. (4) A patient with confirmed curvature, with or without osseous deformity, is so habituated to the vicious position that his attempts to improve the spine increase the deformity, unless instructed by the surgeon. (5) Exercises of the spinal muscles with or without resistance by the surgeon while the patient is in the improved position are absolutely necessary. (6) Good positions should be assumed at all times, especially in sitting, by means of suitable chairs. (7) Moderate walking is beneficial. (8) Lying prone or supine is not curative, as the spinal muscles are not strengthened by it. (9) All spinal supports, where the patient can by an effort maintain an improved position of the spine, even for a few seconds, are injurious or useless. (10) Swinging by the head does not strengthen the spinal muscles. (11) By avoiding all vicious positions, by good ones being shown and maintained, and suitably prescribed exercises carefully practiced, better and quicker results are obtained than by any other treatment hitherto proposed. Mr. Roth illustrated his remarks by reference to the case of a female student at the London Academy of Music, aged eighteen, who consulted him on March 4th, 1882. Up to four years ago she was strong and well, then, without any apparent cause, she began to stoop and have backaches. Becoming gradually worse a surgeon examined the spine, and finding curvature ordered the patient to lie down for two hours daily. At the end of a year, as the patient became worse, an ordinary steel support with arm crutches was ordered. This had been worn for two years when she consulted Mr. Roth, the patient having become more deformed and suffering more. On examination the patient presented confirmed lateral curvature, the whole spine being convex to the left, the right scapula more than two inches below the left, with considerable exaggeration of the cervico-dorsal antero-posterior convexity, causing poking of the head, flat chest anteriorly, and undue prominence of the abdomen. There was slight permanent rotation to the left of the lumbar vertebra, and slight increase of the convexity of the left ribs posteriorly. She could be placed in an almost normal position, and maintain it by a great effort for a few seconds. The spinal support was ordered to be left off completely, and a few simple exercises shown. On Dec. 8th he found the state of the spine unaltered from the first visit. Mr. Roth maintained that no instrument yet invented can put or keep a patient in the improved position shown in the three photographs exhibited. On Dec. 23rd the patient began daily treatment. On Jan. 13th she passed the whole day without backache for the first time for two years, and on January 16th the dressmaker had to widen her dress five inches across the chest. On examining the back, the habitual position was found decidedly less deformed than on Dec. 20th. Her appetite was much better, especially at breakfast. Since Jan. 20th the patient has been practicing a prescription of which the "keynote" is a position with the right arm directed upwards, the left arm outwards, while the spine is rotated to the

right and slightly flexed laterally to the left. The patient has continued to improve up to the present time, and there was reason to expect a practical cure at the end of three months' treatment. Measurements of the arcs of the different curves in a case of lateral curvature the author thought very misleading if a note be not also taken of the improvement which can be effected by the patient's voluntary effort properly directed by the surgeon. Lastly, rough-and-ready gymnastic treatment, such as advising a patient to swing on a trapeze with one hand higher than the other, or to use a skipping-rope, is not to be compared in efficiency with systematic localized exercises (medical gymnastics), while the patient is placed in the improved position. The latter continued, with attention to the avoidance of all injurious positions during the day, constitute the most successful and rapid treatment of lateral spinal curvature.

Mr. Herbert Page related a case of Tabetic Arthropathy in which the Tarsal Bones of both Feet were involved. This case was originally shown in the museum for living specimens at the International Medical Congress. The patient was a man, aged thirty, who, in October, 1880, began to have swelling of his right leg and ankle. The foot gradually increased in size, and when first seen in February, 1881, there was great enlargement in the region of the tarsal bones, which were freely movable on one another in any direction. A month later, broken corns appeared on the sole, with an ulcer on the big toe. These sores were absolutely painless; as, indeed, was manipulation of his foot; a circumstance which led to the discovery that the patient was the subject of *tabes dorsalis*, the knee-jerk being absent, and the pupils presenting the "Argyll-Robertson phenomenon." There was no ataxia in gait. While under observation the left foot became affected in a similar way to the right, very rapidly and without pain. Four years previously he had severe lightning pains down the limbs, and two years before he had an illness called "nervous debility," of which the most noticeable feature was profuse vomiting every day for nine months; which began and ended quite suddenly without known cause as to its origin or its termination—a true gastric crisis. Attacks of a similar kind have occurred since the patient has been under the author's observation, and each of them has begun with a severe rigor, and been marked by the passage of large quantities of blood in the urine, associated at the same time, with profuse vomiting, diarrhoea, and increased lightning pains. The patient has now been free from these attacks for some months, and the swelling of the feet has subsided. The feet, however, are strangely deformed, owing to an alteration in the relative position of the affected bones. The other symptoms of *tabes dorsalis* remain the same, but there is still no ataxia. Only one instance of this particular form of arthropathy had been seen by M. Charcot. Though rare, it had, however, many features in common with the arthropathies affecting the larger joints. One foot of his patient would in all probability have been removed—so bad was it—had not the cause of the affection been accidentally revealed by the symptoms. The arthropathy has subsided, however, and left a useful, though deformed, limb. The occurrence of attacks of paroxysmal hæmaturia was a striking feature in this case, and the association thereof with the other symptoms of a crisis seemed to indicate that it was not less a symptom of the disease than the vomiting, the diarrhoea, and the joint affections. The history may suggest a new line of observation, and inquiry in the study of these cases of paroxysmal hæmaturia or hæmaturinuria.—Dr. Althaus protested against the expression "tabetic;" the ad-

jective should be "tabid;" it was important to be correct in a term which was likely to be much used.—Dr. Buzzard said the case was very interesting from many points of view, one of which was the occurrence of attacks of paroxysmal hæmaturia. He had never met with any similar case. But might it not happen that cases of so-called paroxysmal hæmaturia were really cases of *tabes dorsalis*, in which this one symptom masked all the others? He was also interested in the association of gastric crisis with this arthritic condition. This association he had observed in a large number of cases. He referred to one of these cases lately recorded in our columns, in which there was a healed perforating ulcer of the foot. He had lately met with another form of trophic disorder, an ecchymosis under the big toe-nail without any injury, leading to shedding of the nail.—Dr. Mahomed said he had under his care a patient with locomotor ataxy who had polyuria, he had been passing 106 ounces per diem, specific gravity 1004; this was evidence of renal neurosis.—Mr. Page said he had recently read a thesis on spontaneous fall of toe-nails, and changes in their shape occurring in "tabid" cases. "Nephritic crisis" had been applied to attacks of extreme colicky pains in the kidney in a case of locomotor ataxy, associated with entire suppression of urine with great albuminuria, between the attacks. It was easy to see that from the attacks of hæmaturia coming on with a rigor the true nature of such a case might be entirely overlooked, and its origin attributed to cold.

OBSTETRICAL SOCIETY OF LONDON.

A MEETING of the above Society was held on March 8th, Dr. H. Gervis, President, in the chair.

Cast of Female Bladder.—Dr. Aveling exhibited this specimen. The patient suffered from retention of urine for four days after delivery. This was relieved by the catheter, and the bladder was subsequently washed out. Three weeks after delivery the cast exhibited, which was formed by exfoliation of the vesical mucous membrane, was passed. Fifteen months afterwards the patient still suffered from incontinence of urine; but, except for this and a recto-vaginal fistula, was well.—Mr. Hopkins Walters had seen a similar case, due to retention, which had lasted four days, from retroversion of the gravid uterus. The cast was passed the sixth day after relief of the retention. The patient recovered without further vesical trouble.

Fibroma of Ovary.—Dr. John Williams exhibited a solid ovarian tumour removed by him. It was pear-shaped, about three inches in diameter at its thickest part, and consisted of white fibrous tissue, with areas of mucoid degeneration and in the centre extensive calcareous change.—The President remarked on the rarity of such tumours.

Tumours removed by Abdominal Section.—Dr. Bantock showed a dermoid ovarian cyst, a specimen of double hydro-salpinx, and five uterine fibroids, which he had removed by abdominal section. In three of the cases the tumours, weighing upwards of 7 lb., 4 lb., and 2 lb., respectively, were removed on account of pain, there not being much hæmorrhage. In one, on account of hæmorrhage, he removed the ovaries. This was followed by metrorrhagia lasting four weeks, and, at first, diminution in the size of the tumour. Three months after operation the uterus had regained its former size; the hæmorrhage recurred, and gradually increased, and therefore he removed the tumour, which weighed 3 lb., and presented cystiform degeneration. In the remaining case the ovaries had been

removed about a year previously by another surgeon, but this had been followed by increase in the hæmorrhage and no diminution in the size of the tumour. He (Dr. Bantock) therefore removed it. In cases such as these he thought oophorectomy could not come into competition with hysterectomy, for cystiform degeneration of uterine fibroids was as surely fatal as ovarian cystoma. He could not concur in the opinion that hysterectomy should only be done when oophorectomy had been tried and had failed. He did not think much was gained by ligation of the uterine arteries; the collateral circulation was too efficient. He had now performed twenty-two hysterectomies, of which twenty had recovered, in none of which had "full antiseptic precautions" been used.—Mr. Knowsley Thornton thought Dr. Bantock's cases illustrated the value of oophorectomy. Removal of the uterine appendages had in each case been only imperfectly accomplished, and this accounted for the persistence of hæmorrhage. Moreover, the tumours were undergoing atrophy, the cyst formation being part of the degenerative process. He had seen these patients when hysterectomy was performed, and their condition of health seemed to him so good that without further information he did not understand the reason for the operations. He thought that the condition of patients was not so good after hysterectomy as after oophorectomy; after the former there was a possibility of a permanent fistula, or of a ventral hernia.—Dr. Savage said the condition of Dr. Bantock's patients was such as to justify the operation. The mortality was one in eleven, not greater than that of ovariectomy. Battey's operation he thought detestable.—Mr. Doran thought long series of after-histories were needed before the profession could judge between the two operations.—Dr. Routh thought oophorectomy (except as a *pis aller*) a shameful, and often useless, operation, unsexing the patient, and failing to cure. He thought evidence was required in support of Mr. Thornton's assertion that the operations were imperfectly done. The atrophy of the tumours might be due as much to the age of the patients as to the oophorectomy. The ill-health of the patients was such as to justify the operations in Dr. Bantock's cases.—Dr. Wynn Williams had sent two of Dr. Bantock's patients to him, and thought the operation was thoroughly justified in each.—Dr. Bantock said the amount of hæmorrhage was such as to make the patients hopeless invalids, and he thought this justified the operation. Examination of the specimens showed that the ovaries had been thoroughly removed.

Uterine Polypi.—Dr. Wynn Williams exhibited two polypi, one fibroid, the other of mucous, intermixed with fibrous tissue. The specimen in the second case was referred to a committee for examination and report.

The President then delivered an address, for which a vote of thanks was moved by Dr. R. Barnes, and seconded by Dr. Graily Hewitt.

Turning in cases of Contracted Brim.—A short paper on this subject by Dr. Burchell was read. The author described a class of cases in which after several easy deliveries, the birth of later children became difficult. Out of 8,000 deliveries he had met with forty-five such cases. He attributed the progressive difficulty of labour to deposit of bone on the sacral promontory. In these cases attempts at forceps delivery often failed, and then perforation was resorted to. He believed they were better treated by turning. Out of forty-five cases so delivered by him, he had saved the children in thirty-eight. He thought this practice was new when he first adopted it, and that still its advantages were insufficiently recognized.—Dr. Robert Barnes had largely practiced turning in

cases of minor degrees of contraction of the pelvic brim, and formerly placed it between the forceps and craniotomy. He now thought there were few cases in which Tarnier's forceps were not superior. Dr. Champney's said increasing difficulty of successive labours was accounted for by increasing size of the children, and diminished power in the mother. Progressive diminution in the size of the pelvis had never been verified by measurement. Either forceps or turning, if applied to all children, would show a large percentage of success, although not really beneficial.

A meeting of this Society was held on April 4th, Dr. Gervis, President, in the chair.

Knotting of Umbilical Cord.—Dr. Godson exhibited a four months' fetus with placenta, showing a knot in the umbilical cord, with atrophy of the cord on either side of it, leading, he believed, to the death of the fetus.

Dermoid Cyst.—Dr. Edis exhibited a dermoid cyst removed by him. It was so extensively adherent that it was difficult to determine whence it had sprung. Both ovaries and broad ligaments were removed with it. The patient recovered.

Hernia of a Uterine Fibro-Myoma.—Mr. Knowsley Thornton exhibited a uterine fibro-myomatous tumour weighing 11½ lb., removed by him. The abdomen had been opened some years previously, but the operator, finding the tumour uterine, closed the wound. A hernia of the tumour resulted; it became adherent, ulcerated, and bled. Mr. Thornton removed it with the uterine appendages. The tumour was of the soft kind, and, he thought, might have been cured by removal of the uterine appendages; but it was impossible to close the wound without removing the uterus. He believed the case unique. The patient was doing well.

Axis-traction Vulsellum Forceps.—Dr. Robert Barnes showed a sessile submucous fibro-myoma and a new axis-traction vulsellum forceps which he had devised and used for its removal. By this instrument the tumour was dragged within reach without undue or misdirected force, and room was left for manipulation in front. He thought this application of the principle of Tarnier's forceps would prove of great value.—Dr. Aveling had invented and published forceps of the form permitting axis-traction ten years before Tarnier's forceps of the same form was made known.—Dr. Heywood Smith suggested that his forceps would be better if the blades were made separable.

Cyst and Tumour of Placenta.—Mr. Mark (for Dr. John Williams) exhibited a Placenta having on its fetal aspect a cyst the size of a Tangerine orange, at the base of which was a tumour, apparently fibrous, the size of an almond.

On the "Pressure of the Femora" and its influence on the Shape of the Pelvis.—This paper, by Dr. Champneys, was then read. After a brief review of the history of pelvic literature, special mention was made of the study of the fetal pelvis by Fehling, which showed that many characters previously supposed to be the result of the operation of mechanical influences after birth were really congenital and antecedent in date to the operation of such influences. The same applied to the rickety fetal pelvis. It followed from this that the scope of mechanical influences as hitherto accepted had to be reconsidered. In considering the influence of the "pressure of the femora" fallacies were pointed out, and all possible sources for this pressure were reviewed. These included: 1. Passive resistances (a) bones, (b) ligaments, (c) couples. 2. Active operations: (a) action of muscles. These were in turn scrutinized, and the

conclusion reached that "the action of the muscles joining the femur and the pelvis is a true cause of the 'inward pressure of the femora,' and is aided by the muscles favoring inversion of the foot." A corollary followed, "that use of the lower limbs will increase the inward 'pressure of the femora.'" In unsymmetrical pelvis, and pelvis in which the acetabula are within the line of the body-weight, other consequences followed. These were illustrated by three figures. The phrase "increased pressure on the overweighted side" was shown to include many different factors.

Dr. Robert Barnes suggested that one factor in producing flattening of the rickety fetal pelvis might be pressure from the attitude of the fetus with the thighs doubled up.—Dr. Matthews Duncan agreed with the paper in the main. Dr. Champneys had given a valuable sketch of the history of the subject, and his special study of the action of femora as a result of body-weight and muscular force made the paper a great contribution to pelvic literature. He (Dr. Duncan) would not give muscular action a paramount position, and for that still vindicated the great force of body-weight.—Dr. Aveling drew attention to a pelvis in the Society's museum, the shape of which was normal, although congenital dislocation of the hip was present.—Mr. Doran thought muscular action in the fetus was a force too slight and intermittent to be capable of altering the shape of cartilaginous bones.—Dr. Champneys agreed that gravity was the most powerful of the forces acting on the pelvis. Although the action of mechanics might have been pressed too far, it was impossible, in the face of the malacosteon pelvis, to upset it. He did not think that the fetal attitude was capable of flattening the fetal pelvis, for the fetus floated in fluid, and therefore was not exposed to any inequality of pressure, and its attitude was not for it one of constraint.

Case of Labour with Atresia Vaginae.—This paper, by Dr. Fancourt Barnes, was then read. The patient was aged twenty-one, pregnant for the first time. The vagina was represented by a cul-de-sac, about one and a half inches deep, at the bottom of which was a pinhole aperture, the orifice of a canal of no larger dimensions leading into the uterus. This canal traversed about two inches of tissue before reaching the uterine cavity. The patient was anesthetized, the canal stretched with a Priestley's dilator, then incised on each side with Simpson's metrotome, and still further enlarged by laceration with the finger. Delivery was then accomplished with Barnes's forceps, it being found impracticable to apply Tarnier's. The operation lasted an hour, and was performed under carbolic spray. Mother and child did well.

The report of the committee upon the specimen shown by Dr. Wynn Williams at the last meeting was read; it was to the effect that the tumour was a submucous fibroid.

HARVEIAN SOCIETY OF LONDON.

At the meeting of this Society, held on March 15th, the President (Dr. E. Symes Thompson) in the chair, Mr. Pepper showed with Mr. Howard Hayward a patient whose upper jaw he had excised. He was admitted into St. Mary's Hospital with a soft, painful, and rapidly increasing enlargement of the left upper jaw. This was at first thought to be due to suppurative within the antrum; but an exploratory incision elicited the fact that the swelling was caused by some solid or semi-solid growth, so it was decided to remove

the upper jaw. This was done by the usual method, the arch of the soft palate being left entire by means of a horizontal incision in front of that structure, the hard palate having been previously divided down the middle line. As the growth involved the floor of the orbit, and reached over to the opposite side through the septum nasi, the removal of bone was necessarily extensive, and the operation proportionately formidable; the patient recovered, nevertheless, without an unfavorable symptom. The growth was of a sarcomatous nature, with round and spindle cells intermixed. On her departure from the hospital the patient was almost toothless and speechless and much disfigured; but since that time an apparatus has been devised for her by Mr. Howard Hayward, which had wonderfully improved her appearance, her articulation, and her masticatory powers. Mr. Howard Hayward exhibited the plate which had effected such an improvement in this patient, and also plaster casts he had taken of the case, showing the very large cavity left from the operation.—Mr. Gant congratulated the authors on the success of their case.

Mr. Malcolm Morris then exhibited some cases of Lupus. The first was a typical case of lupus erythematosus of seven and a half years' standing. The feature of interest in the case was that since the treatment of free scarification of its margins had been adopted, there had been no further extension of the disease. The next was a case of lupus erythematosus of twenty years' duration; the disease had attacked both arms and legs before the case came under the author's observation. The third case was in a boy aged fifteen. The disease, which existed on both sides of the face and on one arm, commenced as a small red spot, which gradually spread, leaving atrophy of the skin in the centre of the patch, while round the margin was a curious raising of the surrounding skin, which seemed to be of a warty nature. A remarkable feature of the case was that the warty margin of the patches varied with the season of the year, being well marked in the spring and summer, but almost disappearing in the autumn and winter. There was a long line of the eruption on the left arm. The boy had five years ago been under the care of Mr. Hutchinson, who had made drawings of his condition. These were shown to the meeting, and Mr. Malcolm Morris pointed out that since then there had been no extension of the disease. Mr. Hutchinson had called it lupus marginatus, while other observers considered it to be ichthyosis.—Dr. Stephen Mackenzie could not accept the third case as one of lupus, he thought it was of a papillary nature and of nervous origin. It was not in his opinion connected with the lymphatics, and there was no destructive lesion, as in lupus.—Mr. Pepper thought it remarkable that if the disease were of neurotic origin there should be an absence of neuralgic pains, and pointed out its irregular distribution on the face as against that theory.

Dr. William Ewart exhibited a girl, aged eight, who had been for the space of one month the subject of severe convulsive attacks, presenting some of the features of Hystero-epilepsy. There was no hereditary history of insanity, epilepsy, or hysteria. The exciting cause appeared to have been a fright, but a predisposing influence was also noted in the shape of a recent attack of diphtheria. A strongly hysterical element was traceable throughout the case. The admission of the patient into the Belgrave Hospital for Children was followed by rapid improvement. Moral management and the administration of bromide of potassium were the chief methods of treatment resorted to in this instance.

EPIDEMIOLOGICAL SOCIETY.

A MEETING of this Society was held on March 7th, Dr. George Buchanan, F.R.S., President, in the chair.

Surgeon-General Murray read a paper on the Delhi or Oriental Sore. He stated that this disease had attracted little attention in India previous to 1857-58, at which time the palace and city of Delhi were occupied by European and native troops. The military cantonment had previously been situated two miles outside the city walls, and this disease was rare amongst the troops, although cases were occasionally heard of there, and at Mooltan, and Lahore. After 1858 it was brought prominently to notice, as the troops in garrison at Delhi were attacked with great severity; from 40 to 70 per cent. were admitted into hospital suffering from the sore, whilst nearly half the regiments had slight sores, which were treated out of hospital. The disease was very tedious and troublesome, though only in two or three instances fatal. When severe or situated on a joint, it rendered the men unfit for duty. In 1865 the Government of India appointed a Commission to investigate the disease, to trace out its origin, and to point out a remedy. The author was President of this Commission, and he thus had an opportunity of accurate observation of the disease. It appears on exposed parts of the body; at first as a small pimple, like an irritated mosquito bite, and remains in this state for several days or weeks, sometimes even for months. It then slowly increases and a thin fluid escapes from the top, which dries and forms a circular scab, gradually increasing in size and thickness. When this scab is removed an indolent ulcer is exposed, with undermined edges and lobulated granulations in the centre, in healthy subjects like raspberries, but paler and more blue in cachectic cases. These ulcers when very broad show signs of cicatrizing from the centre; in all there remains a depressed cicatrix after healing. This is the natural course of the disease, which may last from six months to two or more years, when uncomplicated with leprosy, secondary syphilis, miasmatic fever, or a cachectic state of the body produced by other diseases or famine. When such diseases exist they are aggravated and rendered more fatal. The Delhi sore appears identical with the "yaws" of the West Indies, "parange" of Ceylon, and the "bouton" of the eastern and southern shores of the Mediterranean. At Delhi, Mooltan, and Lahore the disease is endemic, and confined to residents within the city walls. The Commission at Delhi, after patient investigation, formed the opinion that the Delhi sore is a cutaneous disease, of parasitic origin, and that the foul water of the city wells was the habitat of this parasite. The water of all these wells was excessively impure. In some, according to analysis at this time, the water contained from 45,375 to 123,200 grains of organic matter per gallon. This germ, or parasite, finds entrance to the body during bathing or washing through an opening in the cuticle caused by any abrasion of the skin, and the most frequent channel is probably the surface of an irritated mosquito bite, as the ordinary situation of the sores is on an exposed part of the person, as the face, hands, and arms, while the hairy scalp escapes. The germ, once introduced, develops in the cutis vera, exciting inflammation in the surrounding parts, and the sore results. Attempts were made to detect the germ microscopically, but in vain. Since then Dr. Flemming and others have supposed they have discovered it; but, as Drs. Lewis and Cunningham, after careful examination, failed to see it, implicit confidence cannot be placed in less experienced

observers. To determine the contagious nature of the disease six natives were inoculated from a dry crust; but no disease followed. They were then inoculated from a fresh sore, and twenty-three out of twenty-four punctures showed irritation, like that from vaccination, on the third day, which gradually extended till the sixth and tenth days, when remedies were applied to check the disease in four men, leaving it to take its course in the other two cases. The treatment recommended by the Commission was to avoid using impure water, or, if this be impossible, to boil the water before using it, and to have all wells cleared out every year. The local treatment of the sore is directed to destroy the vitality of the germ by the application of the actual cautery in the earliest stage, and potential cautery—potassa fusa or nitric acid, and carbolic acid or mercury in more advanced stages; following the destruction of the specific disease by simple dressing, and washing with diluted carbolic acid. In the discussion which followed, the President, Sir Joseph Fayrer, Surgeon-General Manifold, Dr. Scriven, Dr. Ewart, and Mr. Long took part.

A meeting of the above Society was held on April 4th, Surgeon-General John Murray, M.D., in the chair.

Dr. G. B. Longstaff read a paper on Phthisis, Bronchitis, and Pneumonia: Are they Epidemic Diseases? The following is an abstract:—The author explained that his object was to examine the Registrar-General's returns in such a way as would make clear their bearing on the solution of the question propounded. As in previous papers, relating to summer diarrhoea and the diseases allied to erysipelas respectively, he exhibited diagrams graphically representing the death-rates for England and Wales from the diseases in question, and certain others in various ways allied to them, during a period of twenty-five years; also showing the same death-rates in London for thirty-three years, compared with a curve expressing the number of cold days in each winter. Many other curves had been pointed out by the author, but only a few had proved useful for the purpose in hand. One diagram showed that the death-rate curve of phthisis deviates but very little from a straight line, resembling in this respect those for cancer, apoplexy, paralysis, convulsions, and fractures. The curves of tubercular meningitis (hydrocephalus), and to a lesser degree tabes mesenterica, resembled the phthisis curve. The phthisis death-rate had fallen 20 per cent. during the last twenty years. The bronchitis curve exhibited considerable fluctuations, but on the average it had risen 81 per cent. during twenty years. Pneumonia gave a curve closely resembling that of bronchitis in many respects, but the average mortality had fallen 20 per cent. The total mortality from all diseases of the respiratory organs, together with phthisis, showed an increase of 5 per cent., indicating that probably many deaths formerly returned as due to phthisis or pneumonia were now classed with bronchitis. Pleurisy appeared to be more allied to rheumatism than to respiratory diseases. From the curves relating to London deaths, it appeared that bronchitis and pneumonia corresponded with the coldness of the winters, but not so closely as might have been expected. Phthisis was but little affected. Curves derived from Messrs. Buchan and Mitchell's paper on the Influence of Weather on Mortality, showing the average weekly fluctuations of the death-rates from various causes in London during thirty years, strongly confirmed the author's conclusions, with the single exception of tabes mesenterica, which gives an entirely different curve from that

of phthisis. In another diagram were exhibited the week-to-week fluctuations of the deaths from bronchitis and pneumonia during the last five winters in London, and their relation to cold; also the same for phthisis during two of the winters. This diagram showed clearly that the pneumonia death curve had a general correspondence with the bronchitis death curve; but it differed in two particulars—viz., the fluctuations were much less, and while it rose in the autumn as rapidly, it fell in the spring more gradually. In the spring of 1879 there was a prolonged high mortality from both bronchitis and pneumonia out of proportion to the severity of the cold; and during the whole winter 1878-9 the two curves of bronchitis and pneumonia corresponded less closely than in the others. The effect of two hard winters upon the phthisis mortality was shown to be remarkably slight. It was noted that for every 1,000 females who died of pneumonia not less than 1,460 males died, whereas in the case of bronchitis the numbers were 1,000 females to 1,104 males, and in the case of phthisis 1,000 females to 1,046 males. Bronchitis caused nearly three times as many deaths in proportion to population in Lancashire as in Gloucester. The mortality was also very high in metropolitan Surrey and Middlesex, West Yorkshire, Warwick, and Monmouth. It was very low in Cornwall, Sussex, Norfolk, extra-metropolitan Surrey, Cambridge, and Gloucester. Pneumonia was most fatal in Lancashire, Monmouth, South Wales, West Yorkshire, Stafford, and metropolitan Middlesex and Surrey; least in Sussex, Wilts, Hants, Bucks, Oxford, North Yorkshire, and Westmoreland. In eight registration counties pneumonia was found to be comparatively much more fatal than bronchitis—viz., South Wales, Gloucester, Rutland, extra-metropolitan Surrey, Bedford, Cornwall, Monmouth, and Cambridge. In ten registration counties bronchitis was found to be relatively more fatal than pneumonia—viz., North Yorkshire, Warwick, Wilts, metropolitan Surrey, Cumberland, Nottingham, Westmoreland, Cheshire, Somerset, and Oxford. The author's main conclusions were: 1. That the mortality statistics of England and Wales did not give any evidence in favor of the view that phthisis is communicable, but they showed, on the other hand, that weather had very little influence on the phthisis death-rate. 2. That while bronchitis and pneumonia were both greatly influenced by meteorological conditions, it was difficult to explain by those conditions alone all the phenomena. 3. That common catarrh was a communicable disease, and that it was probable that very many cases of bronchitis and pneumonia might be looked upon as complications of that or some similar disease of mild character when uncomplicated. 4. That the different incidence of bronchitis and pneumonia on the two sexes pointed to some difference in the causation of the two diseases. 5. That there would appear to be some common factor in the causation of phthisis and tubercular meningitis.

In the discussion which followed Surgeon-General Murray, Dr. Thorne Thorne, Dr. Heron, Dr. Mahomed, Brigade Surgeon Scriven, and Mr. Shirley Murphy took part. Surgeon-Major J. B. White read some comments on the subject by Surgeon-General De Renzy, and added some observations of his own.

—At a meeting of the City Commissioners of Sewers in London, recently, it was stated that the pollution of the Thames by sewage was destroying the passenger traffic on the river and greatly injuring the trade in general of the port of London.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

THE usual monthly meeting of the West London Medico-Chirurgical Society was held on February 2nd, the chair being taken by Dr. Hart Vinen, the President of the Society.

Dr. Hood read a paper on *Dyspepsia*. He maintained that the more our experience of the natural history of disease increases the more we must accustom ourselves to the fact that dyspepsia should be looked upon as symptomatic rather than generic. He drew especial attention to those cases of stomach lesion in which dyspepsia plays such an important part as a symptom, and suggested that in many cases of so-called simple dyspepsia there was a definite lesion of stomach coat. He held that the carefully compiled category of symptoms incidental to ulceration of the stomach suggests that its diagnosis is easy, the very opposite of that being clinically the case. Statistics proved that ulceration of the stomach was of very frequent occurrence, but beyond question the symptoms of ulceration varied very greatly. Although hæmorrhage was a symptom of the utmost moment, it was not judicious to wait for the presence of blood before inferring the existence of ulceration. All writers on the stomach treated ulcer as a chronic disease, but none of them advised such treatment as would be adopted in regard to an ulcer occurring on the surface of the body. In treating assumed ulcer he thought it imperative that the patient be kept in a recumbent posture in order that the stomach walls might be in a state of rest. Where there was much enlargement of the stomach, he generally used a counter-irritant, and he freely prescribed the various preparations of opium in those cases where there was no doubt that the dyspepsia did not arise from hepatic engorgement, as he found that it not only stimulated the bowels, but also made the patient less intolerant of restraint. Such treatment in the early stages of dyspepsia was sure to result well. Where the presence of ulceration was well marked, such treatment should be resorted to as would be insisted on if the ulcer occurred on the surface of the body. He mentioned the case of a lady in whom this method of treatment was productive of the best results.—Dr. Daniel said that three or four years ago he attended a gentleman who had contracted indigestion. He gave calomel and colocynth. But the symptoms increased, the patient became very emaciated, vomited largely, and at last was unable to keep food on his stomach. The blood could be traced in the vomit. Dr. Gull was called in, and inferred that there was ulceration. He continued to get weaker, and became at last a mere skeleton. Enemata of nutritive liquids were given, but eventually he died of exhaustion. There was no post-mortem.—Dr. Schacht suggested that, in addition to rest, he regarded an enema every other day as important. Constipation was an awkward symptom, and the enema by relieving the stomach allowed the opium to do its work.—Dr. Campbell Pope said that he overcame constipation with bismuth in conjunction with belladonna.—Dr. Orton said that he knew of a practitioner who had symptoms of ulceration for thirty-five years, and who at last collapsed from vomiting. The post-mortem revealed ulcers in all stages.—Dr. Hood, in reply, suggested that marked dyspepsia required the most careful examination, for early diagnosis was very difficult. The ulcers were really boils of the stomach, resulting in choked glands. He was strongly of opinion that dyspepsia demanded rigorous treatment.

Mr. C. B. Kestley briefly mentioned a case of Re-

fracture after bony union of a fractured patella had been obtained by bony union, and Dr. James Thompson showed examples of the Beaufort artificial limbs, and also explained their peculiarities and advantages.

NORWICH MEDICO-CHIRURGICAL SOCIETY.

At the meeting on March 6th (Dr. E. G. Barnes, President, in the chair), Mr. Williams exhibited a specimen of Dislocation of the Fifth Cervical Vertebra, in which reduction was effected. The rarity of the injury and its possibility being denied by many eminent surgeons were dwelt upon. Reduction was effected by extension being made from the chin and occiput, while counter-extension was made from the shoulders; the reduction was accompanied by a distinct snap or click. Death occurred on the fifth day. At the post-mortem the fifth cervical vertebra was found dislocated without any fracture of either it or the sixth. Careful manipulation showed it was by no means a difficult matter to reduce the bone, but on cessation of extension the displacement again occurred. The position in which the head had been placed, after reduction, on a pillow level with the injured vertebra, was found to be essentially wrong, as it did not prevent the head and upper cervical vertebrae from being carried forwards, reproducing the dislocation.

Mr. Kidd related a case of Popliteal Aneurism treated with Esmarch's Bandage. The bandage was applied tightly from the toes to the lower end of the aneurism, then loosely over the joint, and again tightly as far as the middle of the thigh. The elastic band was then put on, and the bandage taken off. The treatment was continued for two hours, and the sac appeared then to contain semi-solid clot. Signoroni's tourniquet was applied to the apex of Scarpa's triangle, and the band removed. A strong pulsation was then felt in the sac, owing to the tourniquet not being screwed up tight enough; this was immediately stopped. Gangrene of the foot subsequently took place, and Syme's amputation was performed. The flaps sloughed, and amputation below the knee was then done, the progress of the case from that time being satisfactory. Mr. Kidd considered the gangrene of the foot, which was of the dry kind, to be due not to the elastic bandage, but to embolism, a clot being probably washed out of the sac at the time the elastic bandage was removed from the thigh.

Mr. Cadge read notes of a case of Popliteal Aneurism, cured by ligature of the femoral after compression in various forms had failed. In the course of his remarks Mr. Cadge stated that practitioners apart from hospital practice would probably find the ligature the most useful and ready method of treatment if compression did not quickly cure the disease.

Mr. Prangley read a paper on a form of Dyspepsia which he termed "Climacteric." It occurs in women between the ages of forty and fifty. The symptoms are those of great nervous depression, with pain on the top of the head, noises in the ears, hot flushes and chills, with curious sensations in the abdomen. The dyspeptic symptoms are those of præcordial distress, with palpitation, costive bowels, coated tongue, and foul breath. The treatment consists of the administration of bismuth, bicarbonate of potash, and ammonia adding valerian if the nervous symptoms predominate, followed by quinine, strychnia, and the dilute nitro-hydrochloric acid.

MIDLAND MEDICAL SOCIETY.

The ordinary meeting of this Society was held on March 7th in the Medical Institute, Birmingham, Dr. Malins, President, in the chair.

Mr. Wm. Thomas showed a child with Talipes Equino-varus, which was being successfully treated by means of manipulation and the application of plaster-of-Paris cases.

Mr. Jordan Lloyd showed for Mr. West a Kidney which the latter had removed through a Lumbar Wound four days previously. The patient, a boy, aged fifteen, received an abdominal injury in November last; this was followed by hæmaturia, the development of a lumbar tumour, pus in the urine, and pyrexia. In December the aspirator drew off 55 oz. of purulent fluid from the kidney; this was repeated a week later and followed up by a lumbar incision and the insertion of a drainage-tube. Eighty ounces daily of purulent ammoniacal fluid were passed through the tube. As the patient was rapidly emaciating, nephrectomy was performed. The kidney measured 8 inches in length, 4 inches in breadth, and 3 inches in thickness, and weighed 16 ounces.—Mr. Lloyd also exhibited the Tibia and Fibula removed by amputation from a boy, aged nine years. The specimen showed acute osteitis involving the lower epiphysis of the tibia, the upper end of the tibial shaft being similarly affected. There were no inflamed tissues between these points, but, by extension, there was pus in both the ankle and knee-joints. After removal of the limb at the lower third of the thigh, convalescence was rapid.

Mr. Messiter (Dudley) exhibited a male adult on whom he had successfully ligatured the left Common Carotid Artery to arrest Hæmorrhage from the Tonsil. The history indicated a swelling of the left tonsil, ulceration, and two attacks of copious bleeding. On the second occasion Mr. Messiter tied the main artery, and a rapid convalescence followed. It was thought that the ascending pharyngeal artery was the probable source of the hæmorrhage.

Dr. Suckling showed a living case of Myxœdema. The patient was a woman, aged thirty-five, who had been ill for ten years, the first symptoms being drawing speech and puffy eyes. The face is now edematous-looking, but does not pit on pressure; the skin is translucent, with a pinkish tinge on each cheek; solid œdema of each eyelid; the tongue, large and pale moves slowly; general integument is dry and rough; hands swollen; lower extremities look swollen, but do not pit; speech slow and words are sturred; locomotion slow, but no loss of coördination; urine pale, of a low specific gravity, no albumen, seventy ounces passed daily; muscular contractions with electricity much below normal; this Dr. Suckling attributed to the bad conducting power of the skin, due to its dry condition and probable infiltration with mucin.

Mr. Messiter (Dudley) read a paper on Trephining in Cases of Injury to the Skull, and gave details of five instances in which this operation had been performed by himself and his colleagues at the Guest Hospital, Dudley. He was of opinion that to trephine early in many cases of cranial injury was, with the aid of Listerism, of the utmost importance and a practice to be commended.

Dr. A. H. Carter read a paper on Certain Variations of the Pulse in Diseases of the Heart, in the course of which he discussed the diagnostic, prognostic, and therapeutic aspects of undue frequency, irregularity, and intermission of the pulse in their relation to different cardiac lesions.

The ordinary meeting of the Midland Medical Society was held on March 21st in the Medical Institute, Birmingham, Dr. Malins, President, in the chair.

Mr. Priestley Smith exhibited a patient suffering from greatly impaired Vision. The periphery of the visual field was of normal extent. The central area was nearly blind, as demonstrated by charts taken with the perimeter. The optic discs were pale, the retinal arteries small. The man had symptoms suggestive of locomotor ataxy; he had also been a heavy smoker for many years. The central amblyopia pointed rather to the effects of tobacco than to atrophy from spinal disorder, but it appeared that there was a progressive atrophy going on, such as accompanies locomotor ataxy. It was suggested that the atrophic process had affected the central fibres first because they were already damaged by tobacco.

Mr. Jordan Lloyd showed two Hernial Sacs removed for the Radical Cure of Inguinal Hernia. One patient, aged fifty, died on the twelfth day of pneumonia; no peritonitis. The second, a child aged two years, had made a good recovery.—Mr. Lloyd also showed a Tumour as large as a hen's egg, which he had removed from the bladder of a man, aged thirty-four. Symptoms had existed for twelve months. The patient was progressing favorably.

Dr. Barling exhibited an adult patient who by a fall had torn the ligamentous union of an old fractured patella. By a longitudinal incision over the bone the fragments had been laid bare, refreshed, and then approximated by a single silver wire suture, which was cut off short and left *in situ*. The operation had been performed seven weeks before, and the fragments were in good position, and in the course of time Dr. Barling hoped that a solid osseous union would take place.

Dr. Leslie Phillips exhibited a Heart weighing thirty ounces, the seat of ulcerative endocarditis on the aortic and mitral valves. The aorta was ulcerated through an inch above the valves; the pericardium contained several ounces of blood, and each pleural cavity half a pint.

Dr. T. Nelson showed a calculus, more than half an inch square, which had been passed by a woman per urethram.

Dr. Simon, in a paper on the Treatment of Ringworm, advocated thorough and vigorous measures so long as a black spot or a stumpy hair remained; and, when necessary, suitable constitutional remedies. For local application in recent cases sulphurous acid and glycerine and carbolic acid pomade were useful. Epilation was also often necessary. For chronic cases oleate of mercury and croton oil, properly applied as directed by Dr. Alder Smith, would generally effect a cure.

Mr. Jordan Lloyd read a paper on a method of Controlling Hæmorrhage in operations at the Hip-joint. After the limb to be operated upon has been emptied of blood, a pad is placed over the external iliac artery, and a double piece of a flat elastic tourniquet applied, so as to pass internal to the tuber ischii across the pelvic ramus, parallel to and above Poupart's ligament, to a point above the iliac crest; the posterior half of the ligature crosses the sciatic notch and over the buttock, to meet its fellow above the crest. The tendency to slip down the limb is prevented by the hand of an assistant embracing the bandage. Mr. Lloyd quoted seven cases, three of which were amputation through the hip-joint, in which this method had been employed with every success. The advantages claimed for this plan are that it is so simple that no special skill is required to apply it, that no injury is done to the abdominal or pelvic contents; that it controls, without stopping, the

hæmorrhage at a point nearer to the seat of operation than does any other plan now in force.

ACADEMY OF MEDICINE IN IRELAND.

MEDICAL SECTION.

A MEETING was held on January 19th, Dr. William Moore, President of the College of Physicians, in the chair.

Living Specimens.

Mr. A. H. Benson exhibited a case of Hard Chancre on the Upper Eyelid; and Dr. J. Magee Finny, a peculiar case of Vesiculo-tubercular Disease of the Skin of eighteen years' standing.

Specimens exhibited by Card.

Dr. A. W. Foot exhibited drawings of Facial Chromidrosis; Dr. H. Kennedy, Urinary Calculus; Dr. C. I. Nixon, Aneurism of Arch of Aorta obliterating Arteria Innominata; Dr. H. C. Tweedy, Heart showing Vegetations on the Mitral and Aortic Valves; and Dr. F. J. B. Quinlan (1), Bacillus of Tubercle in Sputum, and (2), Bacillus of Tubercle in Lung Tissue.

Empyema, with Notes on Antiseptic Fluids and Drainage-tubes

Dr. Richard A. Hayes first read a paper on a case of Empyema treated by the Radical Method, with notes on some antiseptic fluids employed. After some observations, pointing out especially the great danger of producing general anæsthesia in cases of intended operation on large fluid effusions in the thoracic cavities, he mentioned the particulars of the case. A man, aged twenty-two, was the subject of right empyema of eighteen months' standing, with severe hectic and wasting. On his admission to Stevens' Hospital, the pus was thrice removed by aspiration, and the cavity washed out with carbolic solution without effecting a cure. An intercostal incision was then made and a large cannula introduced, the pus draining away into pads of oakum placed over the opening and the cavity washed out daily with antiseptic solution by means of an elastic catheter. The case progressed favorably, with the exception of a few complicating circumstances, and the patient was ultimately discharged and went to the country, a sinus only remaining unhealed. During the treatment of the case the following washes were used:—1 per cent. oil of eucalyptus, 2 grains; 1 ounce, or less than $\frac{1}{2}$ per cent., carbolic acid; 2 per cent. boracic acid; and 1 per cent. salicylic acid. A careful record of the morning and evening temperatures having been kept, the results obtained from the use of the different antiseptics were as follows:—Oil of eucalyptus (1 per cent.), morning temperature 98.8° F.; evening temperature 100.4°. Salicylic acid (1 per cent.), morning temperature 98.3°; evening temperature 99.5°. Boracic acid (2 per cent.), morning temperature 98.2°; evening temperature 99.4°. Carbolic acid ($\frac{1}{2}$ per cent.), morning temperature 97.8°; evening temperature 98.7°. The foregoing temperatures are averages, the periods of observation being carefully selected so as to be free from complicating influences which might affect the fever curve. During the entire of the later stages of the case, carbolic acid wash was used, and the temperatures were uniformly identical with the result of observations in the early stages. The results, therefore, showed a marked advantage as regards the hectic obtained by the use of an exceedingly dilute solution of carbolic acid. That the carbolic acid had this distinct effect was proved by a trial irrigation of pure water, an even temperature of 100° following its use.

Dr. Purser then described a case of Left Empyema. The patient was a ship's steward, aged thirty. The disease was at first latent; but after nine months he was admitted into hospital, when he was tapped, and subsequently a drainage-tube inserted. His condition continued satisfactory for some months, when severe fever supervened, at first of a hectic character, but soon becoming continuous. Death ensued about three weeks from the commencement of the febrile symptoms. The compressed lung was found to contain air, and to have maintained its vesicular structure unimpaired. The cavity of the left pleura was much diminished. There were three wedged-shaped embolic patches in the spleen, which were softened and purulent. There were no other evidences of pyæmia. Professor Purser directed attention to (1) the prolonged latency of the disease, and to the slight distress, notwithstanding the compression of the lung and the displacement of the heart, which beat in the right axilla; (2) the advantages and disadvantages of different kinds of drainage-tubes in facilitating discharge, and preventing putrefaction; (3) the aseptic fever in the sense of Volkmann and Genzmer, from which the patient suffered at intervals, as contrasted with the septic fever from which he died; and (4) the apparently slight injury done to the lung by the prolonged compression from the effusion.—Dr. Bennett called attention to the risk of injecting the pleural cavity at an early stage, when fever and dyspnoea were present. He advocated a local anæsthetic and the use of the spray in the radical treatment of empyema.—Dr. Finny corroborated Dr. Purser's statement as to the entire absence of fetidity of the discharge during the time the patient was under his care, as well as at the post-mortem examination. Three weeks before death, the initial period of the fever, much pain was complained of in the left hypochondrium, and marked the occurrence of the embolic infarctions of the spleen. Fetidity of the pus was not induced by the use of a simple rubber tube unprotected by any antiseptic; and it was a question for consideration if a period did not arise in the course of such cases when antiseptics might with safety be dispensed with.—Dr. C. Nixon advocated tapping in cases of empyema instead of at once employing the radical treatment. He detailed a case in which the latter operation was performed without the spray, and as the fluid next day became fetid he washed out the cavity with good results.—Dr. W. G. Smith disputed Dr. Hayes' conclusions as to the advisability of washing out the pleura with antiseptics, basing his opinion on the ground that the periods of trial by Dr. Hayes were too short, and that fluctuations of temperature in cases of empyema were common.—Mr. Edward Hamilton corroborated Dr. Hayes' view on the advantage of washing out the pleura with carbolic lotion.—Dr. Hayes, in reply, said he was fully cognizant of the danger of using injections, but that the object he had in view was to induce a healthy condition of the pus-secreting pleura, and that the lowering of the temperature in his case was directly due to the use of carbolic acid.—Dr. Purser considered that the only circumstance which justified washing out the pleura was where the discharge was fetid, and continued fetid for some time.

SUBSECTION OF ANATOMY AND PHYSIOLOGY.

The opening meeting of the Subsection of Anatomy and Physiology was held on Feb. 1st, the President of the Section, Dr. Alexander Macalister, F.R.S., occupying the chair.

Exhibition of Specimens.

Dr. D. J. Cunningham exhibited frozen sections

of various parts of the human body. Dr. P. S. Abraham exhibited (1) a specimen illustrative of the occurrence of two Superior Venæ Cavae in the human subject, and (2) sections of certain Tissues in lower animals. Mr. T. F. Knott exhibited (1) section of human Hair-follicles, demonstrating the connection of Henle's and Huxley's sheaths; (2) Frog's Nerve, showing Lautermann's notches; and (3) termination of Nerve in Frog's Muscle, showing Bremer's "End-dolde."

The President's Address.

Dr. Macalister delivered an address on the History of Anatomical Research in Ireland. Beginning with the ancient Irish medical literature of the tenth and fourteenth centuries, whose anatomical knowledge is borrowed from classical sources, he sketched the progress of teaching and of investigation, touching on the researches of Mullen, Molyneux, O'Halloran, in the seventeenth and eighteenth centuries, and those of Macartney, Colles, and their successors in the present century.

The Refractory Period of the Auricle of the Heart.

Dr. Purser gave the results of some new experiments which he had made on local electrical stimulation of the different portions of the frog's heart. It was found that for the sinus, the auricle, and the ventricle, the law held good that each of these parts is insensible or refractory to single induction shocks during its systole, while, if stimulated during its diastole, it responded by an extra contraction, followed, in the case of the sinus, by a contraction of the auricle and ventricle; in that of the auricle by the contraction of the ventricle. Some observations were made on the circumstances which influenced the rapidity with which the contraction of the ventricle follows that of the auricle. Dr. Thornley Stoker called attention to the extreme practical importance of Dr. Purser's results in explaining how the murmur of mitral stenosis may be sometimes pre-systolic and sometimes post-diastolic.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

At the meeting of this Society on March 1st (Mr. B. Walker, President, in the chair), Dr. Law showed the morbid specimens from a case of Disease of Aortic and Mitral Orifices, where an ossified cystic kidney was found post mortem on the left side. There were no symptoms indicating the condition during life. Dr. Law referred to the rarity of the case, and in answer to a question, remarked that authorities were divided as to whether the kidney was really ossified or simply infiltrated with calcareous plates.—Dr. Law also exhibited a specimen of Cancer of the Pylorus. The cancer was of enormous size, involving quite two-thirds of the pyloric end of the stomach. Dr. Law remarked on the difficulty of diagnosis during life, owing to the absence of symptoms, vomiting being absent for weeks before death, though solid food—e.g., rabbit, was daily partaken of. Hæmorrhage was absent, and pain was, as a rule, slight. The growth had been examined microscopically, and was found to be of well-marked sarcomatous character.

A patient suffering from Charcot's Disease, from Dr. Bartolomé's wards at the General Infirmary, was introduced by Mr. C. Atkin. He was aged forty-seven, and had had for four years lightning pains, ataxic gait, and billous attacks. Last September a well-marked gastric crisis compelled him to keep his bed for several weeks, and on attempting to get up he found that the right knee was swollen, and that he could put no weight on the

limb. On admission into the infirmary the limb was found swollen and helpless, and the tibia and fibula were painlessly dislocated backwards. Mr. Atkin alluded to Volkmann's statement that tabetic arthropathy is really traumatic, and due to the awkward movements of an ataxic patient; and after mentioning the diagnosis between this disease and osseo-arthritis he referred to syphilis as the prime cause, an opinion held by Erb, Gowers, Westphal, Buzzard, and Fournier, though opposed by Leyden and Lancereaux. The bladder symptoms in this case were interesting and peculiar, the urine not flowing readily away through the catheter, but being jerked out by the movements of the diaphragm. The Argyll-Robertson pupil was said to be present, but there was no optic atrophy, the latter condition, according to Dr. Gowers, only occurring in 15 per cent. of ataxics. No case, it was said, with the tripod of symptoms—viz., lightning pains, Westphal's test, and Argyll-Robertson's pupil—had ever been known to recover. The prognosis of the state of the knee was bad, as it came under the class that M. Charcot called "malignant."

Dr. Gwynne read a paper on Infantile Paralysis. After a short historical sketch of the disease, he dwelt upon the pathology of the affection as far as it had been ascertained. He drew a comparison between the symptoms and pathology of this disease with those of progressive muscular atrophy, and suggested the possibility that they were not so closely allied as Charcot endeavored to prove. As regarded the initial fever that ushered in the symptoms, he gave it as his experience that it was rather the exception than the rule. He regarded the etiology of the disease as still very obscure, and thought it probable that many of the cases considered under the common title of infantile paralysis belonged to distinct lesions, and ought to be differentiated. He did not think treatment had much to do with the result; but at the same time thought all the means recommended should be employed, especially dwelling upon the use of galvanism and keeping up artificially the heat of the parts affected. He recommended the galvanic current to be first used, and afterwards, when the limb responded to the faradaic current, that it should also be employed. He generally employed from ten to twelve cells or even more, the positive pole being applied to the spine at or above the seat of supposed lesion and the negative to the limbs after the labial method. The use of injections under the skin of ergotine, strychnine, etc., he had no experience of.

MEDICAL OFFICERS OF HEALTH SOCIETY.

Infectious Disease Hospitals.

At a meeting of this Society, on March 16th, Dr. J. W. Tripe, President, in the chair, a discussion took place on some of the "practical recommendations of the Commissioners appointed to report on hospitals for infectious diseases."—The president said, in opening the discussion, that he believed, from the resolutions already passed at a meeting of the Society, they were all of opinion that the provision of hospital accommodation for persons suffering from infectious diseases should be disconnected from the Poor-law administration, and he should not make any remarks concerning this recommendation. It had been inserted merely to show that, although it was proposed that the Asylums Board, somewhat modified by members elected by the vestries and district boards, should take charge of the sick, it would not be as a part of the Poor-law work. As regards the second re-

commendation, to the effect that the certificate of disease shall be sent to the medical officer of health, who is to satisfy himself that the patient can be isolated at home, and, if not, shall notify the case to the Metropolitan Asylums Board, who will take charge of the patient, he thought a very onerous duty was cast upon the medical officer of health. If he had personally to satisfy himself as to that fact, in a district such as that of Hackney, it would lead to so great a delay in the removal of the patient as to be very injurious to him and would also prevent other necessary work being done; besides which, it might lead to so great a conflict with medical practitioners generally as to bring matters to almost a deadlock. In the event of any legislation on the subject, the meaning of this would have to be more clearly defined. He thought that, as the Metropolitan Asylums Board, as newly constituted, would no longer be connected with the Poor-law authority, and would be bound to provide for all cases, the least complicated method of carrying out the removal of the sick would be for the Board to be required to remove all persons who were certified to them by any registered medical practitioner as suffering from an infectious disease. This would be much better than forwarding the certificate to the medical officer of health, addressed to the offices of the local authority. Of course the notice of disease would have to be forwarded to the local authority, but this duplication of work by the medical practitioner would not be of much moment. Dr. Tripe thought also that the plan would cause less friction with medical practitioners, as the person giving the certificate would be responsible for the correctness of the diagnosis, instead of placing the medical officer of health in the position of a judge on that point. It would also be necessary to have the power of the medical officer of health as to compulsory removal somewhat strictly defined, as he did not think that at present the public would be inclined to place him (the medical officer) in the position of sole judge as to the necessity for this action. As to the third proposal—that if the sick person cannot be isolated by his friends, the medical officer of health will be bound to take all necessary steps for his isolation with power to clear the house of its inmates, and to require the revaccination of all occupants who are not otherwise protected—the President said that if this were done in a few cases, as he considered it might have to be, it would be necessary for the local sanitary authority to provide a kind of house of refuge, where those who were removed could remain until the sick person had recovered. This might be costly in those cases where the breadwinner was attacked, as the family might have to be maintained in the quarantine-house until he died or was sufficiently recovered to be removed. As to the power to require revaccination, there can be no doubt that it should be possessed by the medical officer of health.—The discussion was continued by Dr. Bristowe, Dr. Browning, Dr. Corner, Dr. Dudfield, Mr. Lovett, Dr. Rogers, and Mr. Shirley Murphy.

Editorial.

THE ATTENUATION OF VIRUS.

THE value of the tentative attitude of the scientific mind towards the whole subject of bacterial pathology has been at no time more apparent than at present. There is much contention, especially, in that department which deals with the attenua-

tion of pathogenic bacteria. Toussaint had shown that anthrax blood lost its virulence when treated with carbolic acid or exposed to a temperature of 55° C.; but to Pasteur belongs the great merit of having demonstrated that the bacilli themselves may become changed and attenuated, and, further, that the new functions which they thereby assume are capable of being transmitted. The alleged capability of the spores of certain bacilli to resist the destructive influence of various powerful agencies, although an altogether different and almost perfectly opposed notion to the one with which we are engaged at the present moment, is brought prominently before the mind, because attenuation of virus suggests a practicable way out of a practical difficulty, and at the same time an explanation is afforded which may more or less satisfy the theoretical side of the question. When we speak of the attenuation of a formed micro-organism we mean that such bacilli may become changed in respect of their physiological properties, but not in respect of their apparent morphology; and this is a principle which is fraught with important suggestions for the welfare and progress of hygienic science. It is a generalization supported by innumerable examples that in nature the function precedes the structure. Perhaps from a *a priori* reasoning we should come to the conclusion that the one is coetaneous with the other; but so far as we have yet gone, direct observation has been unable, possibly because of the imperfection of our powers of investigation, to support that notion.

Koch has maintained, in his reply to Pasteur on anthrax vaccination, that, as to attenuation in general, he is unable to find evidence of its occurrence for any other virus than that of anthrax. If we recognize the grand principle of attenuation of virus as resting on a sufficiently firm basis, we are hardly yet in a similar satisfactory position as to the *rationale* by which such modification is brought about. As everyone knows, M. Pasteur seeks the explanation of this pregnant fact in the oxygen of the atmosphere, and the process is an essentially chronic one. Koch does not concur in the hypothesis put forward by Pasteur, but thinks that all the evidence at present adduced goes to show that the real agent is a high temperature. It is also regarded by Koch as probable that chemical influences and various other conditions may have the faculty of attenuating the virus. In this connection some remarkable investigations made by M. Chauveau, and recently published in the *Lyon Médical*, are deserving of interest. The method adopted consisted of two chief stages; the virus used was the blood from cases of charbon. Vessels containing sterilized *bouillon* were inoculated with some fresh anthrax blood containing bacilli. These vessels were then placed in a chamber kept at an even temperature of 42° to 43° C.; just as in the method adopted by Pasteur, but instead of allowing the fluids to remain there for twelve days, they were removed at the end of

about twenty hours, whence they were placed in another hot apparatus kept at a temperature of 47° C. At this temperature the fluids remained for periods varying from one to four hours or more. The process was then finished. The vitality of the virulent agents was not destroyed, but they had been rendered more or less harmless, according to the duration of the exposure to the greater heat to which they had been submitted. The first part of the experiment corresponded to the period of proliferation of the virus. The treatment in the second stove did not alter the external appearance of the cultures. The multiplication of the filaments and rods was suspended, but the formation of rudimentary spores was not prevented—on the contrary, their multiplication seemed to be favored, or if they were not present, they appeared. Chauveau claims that by this method the attenuation may be graduated at will. This was proved by inoculation experiments on guinea-pigs. Animals vaccinated with the fluid which had not been exposed to the higher temperature invariably succumbed in forty-eight hours, with considerable local œdema. Those inoculations with liquid which had been submitted to the heat for one hour invariably produced fatal results, but the time required was longer. And so forth with the remaining experiments. Chauveau has further demonstrated, what Pasteur had already proved, that the attenuated bacilli could be transmitted. In other words, cultivation of the modified micro-organisms through several generations failed to restore the virulent properties. The discovery of the principle of attenuation is a boon to mankind, not only from the possibility of protective vaccination, but also because it would seem to point out the road whereby we may render harmless those agents which seem to be incapable of positive destruction. It is possible that our disinfecting stoves only attenuate, and do not destroy, the dangerous germs.

GERMS IN THE AIR.

THE efforts of Pouchet to demonstrate the number and the nature of the particles which are constantly floating in the air, as well as the proofs afforded by M. Pasteur that various zymotic diseases, as the cholera of fowls, splenic fever, septicæmia, and others, are of a parasitic nature, have been followed up by M. P. Miquel, who has published his researches in the *Annuaire de l'Observatoire de Montsouris*, near Paris, and a good résumé of them appears in the *Revue Scientifique* for March. In his experiments M. Miquel has employed a slight modification of Pouchet's aeroscope, which consists essentially of an inverted funnel, through which the air is drawn by an aspirator, having a slide covered with glycerine or other sticky material, placed opposite its narrow end, the whole being enclosed in an air-tight case. He first endeavored, by making hourly experiments throughout the day for several years, noting at the same

time the concomitant and antecedent meteorological conditions, as the dryness or humidity and the temperature of the air, the influence of the seasons, and the like, to determine the laws which govern the appearance of the spores of various cryptogams in the air. The results he has obtained are: that the number of such spores diminishes in March and rises in April, it increases to a marked extent in May, and attains its maximum in June. It then slowly decreases to October, but is still considerable in November, and the minimum is reached in December. In the locality of the observatory in which the experiments were made, it appears that, speaking generally, a cubic metre of air contains 7,000 spores of fungi in the months of December, January, and February, 12,000 in May, 35,000 in June, 23,000 in August, 14,000 in October, and 8,000 in November. If, however, instead of taking the average of several years, the successive periods of the same year are taken, the same order and regularity are not always preserved. Thus, the number of germs may diminish, notwithstanding that the temperature rises. In such case the effect is masked by that of another factor, the hygrometric condition of the air. This is only in accordance with what is generally admitted—namely, that the development of fungi is in relation with the varying conditions of heat and moisture, but it is remarkable that the influence of moisture differs with the seasons—that is to say, according to the temperature. In summer, for example, dryness lowers the absolute number of spores; in winter or the cold period, on the contrary, the number rises with dryness of the air. Humidity of the atmosphere produces opposite effects at these periods. Storms occurring during fine weather are followed by a great increase in the number of the spores. Heavy rain purifies the air for a very short time only, for it was observed that in from fifteen to eighteen hours after rain the spores became from five to ten times more numerous than before. Particles of mineral dust and many other kinds of microbes in great measure disappear until the evaporation of the moisture has taken place, enabling them to adhere to foliage and to the surface of the soil.

M. Miquel remarks that the employment of aeroscopes by means of which the existence of the germs of fungi which are injurious to the cereals can be demonstrated in any locality might prove of signal service to agriculture by showing their place of origin and enabling them to be destroyed. From a similar point of view the discovery of the existence of the spores of tinea, of diphtheria, or other contagious diseases in the air might serve to explain obscure and inexplicable circumstances connected with their development and extension. It is impossible to suppose that 300,000 spores can be introduced by the act of respiration into our bodies every day without some being of a noxious character.

The number and even the existence of bac-

teria are points much more difficult to determine, since their minute size renders them almost, if not in many instances altogether, invisible, and it is still more difficult to obtain and to cultivate specimens unassociated with other forms. M. Miquel has invented apparatus of various kinds of which drawings are given in the *Revue Scientifique* for the cultivation of bacteria. He finds that at the beginning of storms rain contains a considerable number of bacteria—fifteen, for example, in a cubic centimetre. This number soon diminishes, but at the expiration of two or three moist and rainy days it often contains more bacteria than at first. Now, as the air is at this time very pure, it would appear that the bacteria can live and multiply in storms, or rather perhaps that during storms the air and moisture of the air can charge themselves as they traverse space with a contingent of germs of very variable nature. At Montsouris, 100 rain-bacteria include 28 micrococci, 63 bacilli, and 9 bacteria; and there appear to be about 80 bacteria in a cubic metre of air. The greatest number is present in autumn, the smallest in winter. The distribution of the microbes in Paris indicates that they proceed from the mud of the streets and from the houses. Thus a cubic metre of air contains 28 at the top of the Panthéon, 45 in the Park of Montsouris, and 462 in the Town Hall of the 4th arrondissement. M. Miquel gives a diagram showing the influence of the prevailing wind on the number of microbes. In this the north wind is credited with 124 microbes, the south with 42, the east with 130, the west with 77, the north-east with 152, the south-east with 74, the south-west with 58, and the north-west with 108. The most impure air, therefore, which blows over Paris comes from the hills of La Villette and Belleville. The extraordinary quantity of microbes contained in water, and especially in sewage water, is shown by M. Miquel in another table, in which he gives the numbers contained per litre—first of the vapor condensed from the air, which contains 900; rain-water, which contains 64,000; water of the river Seine at Asnières, 12,800,000; and sewage at Clichy, 80,000,000. And these numbers, he remarks, are minima, and obtained from the current. As soon as the water becomes stagnant the number rises a thousandfold. Investigations such as these reflect great credit on those who undertake them, and deserve to be repeated in every large city.

THE WORK DONE UNDER THE CONTAGIOUS DISEASES ACT.

THE abolition of compulsory examination of women, and of its necessary sequel, compulsory detention, by the recent vote of the House of Commons, is so important from the hygienic point of view that we have summarized the results that have been obtained since the passing of the Contagious Diseases Acts, so that advocates of a voluntary system like Mr. Childers may be under no

misapprehension as to what voluntary efforts must do in order that they may efficiently take the place of the compulsory clauses.

The advantages claimed by the supporters of the Acts are (1) the prevention of disease and the diminution of its severity in the Army and Navy and among the prostitutes in the places to which the Acts apply, and (2) social improvements in the districts under the Acts dependent on their administration. These social improvements are a reduction in the number of brothels and prostitutes, an improvement in the character and conduct, and a large reclamation of prostitutes generally, and of juvenile prostitutes particularly. The deterring influence of the compulsory clauses on young girls tempted to pursue a vicious life must also be taken into consideration. The number of cases per 1,000 of primary venereal sores admitted to hospital from the regiments stationed in the districts under the operation of the Acts has diminished from 91 in 1867 (the year in which the Acts were first applied), to 35 in 1877, and to 40 in 1878, when the Reserves were called out. Even if we exclude the years since 1873, when Lord Cardwell's order stopping the pay of soldiers in hospital with primary venereal disease came into force, we find that the proportion per 1,000 had fallen to 50. If we compare with these results those obtained from all stations which have never been placed under the Acts, we find that, instead of a continuous and regular fall, we have a fluctuating and irregular decrease from 101 in 1867 to 81 in 1873, 68 in 1877, and 88 in 1878. The large increase in the last-mentioned year is especially suggestive and noteworthy; for whilst 5 per 1,000 is the increase attributable to the Reserves in the protected districts, no less than 1 man in every 12—Reserves and regulars—must have contracted the disease in the unprotected districts. We would particularly call the attention of the advocates for repeal to this fact, as shown at page 5 of the Minority Report drawn up by Mr. Stansfeld. The daily saving in the efficient strength of the Army attributed to the operation of the Acts is calculated by Inspector-General Lawson to amount to 258 men in fourteen places under the Acts only—viz., Devonport, Portsmouth, Chatham, Woolwich, Aldershot, Windsor, Shorncliffe, Colchester, Winchester, Dover, Canterbury, Maidstone, Cork, and the Curragh. From the Army Medical Department Report for 1878, we find that 40 per 1,000 were admitted to hospital for primary venereal sores, while 131 per 1,000 were admitted from fourteen stations not under the Acts, although the average strength in the former stations was 55,813 against 20,749 in the latter. The number of registered prostitutes has diminished from 2,650 in 1870 to 1,879 in 1880, and this decrease has been fairly uniform; and the amount of disease checked by compulsory periodical examination—the vital part of the legislation—may be estimated from the following statistics of the ratio of cases of disease per 100 examinations

made by the visiting surgeons, copied from the Report for 1880 of the Assistant Commissioner of the Metropolitan Police:—

1865—76·24 1869—13·90 1873—7·62 1877—7·40
 1866—66·40 1870—8·19 1874—6·97 1878—7·65
 1867—59·20 1871—7·55 1875—6·26 1879—8·05
 1868—39·77 1872—8·40 1876—6·41 1880—8·75

A reduction from 76 per cent. in 1865 to 7 and 8 per cent. during the past ten years is thus shown. The consequences to the health of the community of such a diminution must be so evident to every one, that even though he may be prejudiced against the Acts on other grounds, he will be amazed at the recklessness of the Legislature in vetoing the compulsory clauses, and, by removing the one essential condition on which their benefit depends, practically repealing the Acts. Their value in the prevention of disease is shown, not only by this reduction, but by checking much of the disease that is imported into the districts from places outside the Acts; for in 1877 61·3 and in 1880 66 per cent. of the women who were known to have come into the protected districts from outside places were found to be diseased on their first medical examination. It is in detecting these cases that the compulsory clauses are especially valuable, and we fail to see how any substitute for them can be found. In two years only, 786 diseased prostitutes have been stopped from pursuing their career by being compelled to undergo a medical examination, and surely anyone who is acquainted with the ravages of syphilis, and its remote effects upon, not the individuals only, but their descendants, must see herein an ample justification for restraining the civil liberty of the subject. We shall refer to the social improvements due to the administration of the Acts in another article.

WHITE LEAD POISONING.

STRINGENT measures must be adopted to stop the wholesale poisoning caused by neglect, or the inadequate enforcement, of precautionary measures among the workers in white-lead manufactories. The matter is assuming very grave proportions, and there is little doubt but that the evil is greatly on the increase. We have before us a copy of communications addressed to the Secretary of State, joined to a report by Her Majesty's Chief Inspector of Factories, upon the subject, and which has been presented to both Houses of Parliament. These communications reveal a state of affairs that is simply appalling. In one metropolitan union alone we learn that in twelve months no less than thirty cases had been admitted into the workhouse infirmary suffering from white-lead poisoning. When we reflect that this only represents a small proportion of cases—chiefly those disabled by the disease, and who have received more or less permanent injury from the effects of the poison, and does not include the acute cases which are treated at the hospitals and dispensaries of the district—

(6)

the extent to which the injurious action of lead on the operatives engaged in its manufacture can be imagined. We have already dealt fully with this subject, and have expressed our opinion that a complete remedy is the carrying out in a most stringent manner the precautionary measures which have been shown again and again to be a sufficient protection against the introduction of lead into the system. The Commission we appointed in 1874, to inquire into the influence that certain chemical manufactures had on the health of the operatives engaged, found that the proportion of cases at the various manufactories varied considerably. In those where rules were framed and the provisions contained in them insisted on, the cases of plumbism were infrequent, limited generally to acute cases among new hands, who were not acquainted with the dangers of their occupation and had not learned to appreciate the value of the protective measures enjoined. In some of the best managed factories our Commissioners found workpeople who had been twelve, fifteen or eighteen years continuously working in white lead without exhibiting a trace of deposit on their gums, and who had never suffered in the slightest degree from plumbism. What can be effected in one or two establishments may be done in all. It is only a question of expense, and the choice is whether the cost falls on the manufacturer in providing the necessary appliances and machinery for the adoption of preventive measures, or on the ratepayer for the maintenance of the poor wretches paralyzed from the effects of this deadly trade. If the manufacturer were made responsible for the maintenance and expenses of treatment of all cases of plumbism originating in his workshop, we should speedily find the disease diminishing.

Reviews and Notices of Books.

The Voyage of H.M.S. "Challenger." Zoology, Vol. IV. Prepared under the Superintendence of the late Sir C. WYVILLE THOMSON, and now of JOHN MURRAY. Longmans & Co. 1882.

[FIRST NOTICE.]

THIS volume commences with a brief account of the life and labors of Sir Charles W. Thomson, who, though he had attained to very high eminence for his scientific work, died at the early age of fifty-two. He was elected to fill the chair of Botany in Aberdeen at a time when most men are still engaged in learning the rudiments of their profession; at twenty-three he went to Cork as Professor of Natural History; in 1854, when still under twenty-five years of age, he was appointed Professor of Mineralogy and Geology in Belfast, and shortly after Professor of Natural Science. He took part in the *Porcupine* and *Lightning* expeditions, and subsequently was the head of the *Challenger* expedition, on his return from which, in 1876, he was knighted. He received many honors from home and foreign Societies, and after a severe illness in the summer of 1879, died at

Bonsyde, near Linlithgow, in 1882. A list of upwards of forty of his principal publications is appended to the memoir.

The contents of this volume are: (1) A Report on the Anatomy of the Petrels (Tubinares), by W. A. Forbes. (2) Report on the Deep Sea Medusæ dredged during the voyage, by Ernest Haeckel. And (3) Report on the Holothurioides, Part I., by Hjalmar Théel.

The account of the petrels, by Mr. Forbes, whose long silence since his arrival in Western Africa is beginning to cause much anxiety to his friends, contains much new information, for, as the author observes, the group of petrels has scarcely been examined anatomically, partly owing to their rarity, and partly to their peculiar habits, which prevent their being readily obtained, either dead or alive. The majority of the group inhabit the little-visited oceans and islands of the Southern hemisphere, and are only known from skins or skeletons, the great size of many of them rendering it impracticable for any ordinary collector to bring their bodies home. Professor A. H. Garrod, who, at the time when the organization of the *Challenger* expedition was being completed, was Prosector of the Zoological Society, recommended that special attention should be paid by the staff of naturalists to the formation of a collection in spirit of these oceanic birds, and though he unfortunately did not live to investigate their structure, a very large collection of these birds has been obtained, and their examination and description have fallen into good hands. Mr. Forbes appears to have had seventy-four specimens, belonging to twenty-two different genera, for examination, and has aimed, not at giving a detailed description of the structure of any particular petrel, but at describing the most important deviations from the ordinary Avian type, and to compare the members of it with each other and with other groups of birds in those points of their structure in which experience has shown birds to differ from each other.

The order Tubinares derives its name from the peculiar prolongation of the external nares into a cylindrical tube lying on the dorsal surface of the beak, and opening by one or two apertures. In the Oceanitidæ and smaller species of Procellariidæ, the nasal tubes quite coalesce, in the former presenting a circular aperture with scarcely any median septum, when looked at in front, whilst in the Procellarian genera it is oval and distinctly double. The legs are always bare of feathers for some distance above the tarsal joint, and the scutellation of the tarsi presents minor peculiarities in the two sub-orders. The hallux is always small, and quite absent in Pelecanoides. The pterylosis, or disposition of the feathers, seems to be on the whole very uniform. The ordinary number of the rectrices is twelve, though in *Ossifraga* there are sixteen. The number of primary remiges is always ten, but that of the secondaries varies. The form and arrangement of the stomach and intestines present several peculiarities, and are very similar throughout the group. The mucous membrane of the palate presents several longitudinal rows of pointed retroverted papillæ. The palate is cleft for about half its length by a narrow median fissure, fringed with small spines, and dilating behind into the opening of the posterior nares, and behind this is the linear opening of the Eustachian tubes. From the fore part of the median fissure a sharp median ridge runs forward with four or five strong conical spines on its posterior part. Other spines are found on the sides of the palate. The tongue is sometimes, as in *Ossifraga*, of considerable size, and more or less covered with spines, the oesophagus capacious and distensible, but without

a crop. The proventriculus is very large, reaching nearly to the posterior extremity of the abdominal cavity, and lying to the left side of the stomach and the mass of intestines; it opens by a slight aperture into the stomach or gizzard. This is small, globular, and muscular; it was nearly always found full of the horny beaks of Cephalopoda. The duodenum presents a peculiar upward curve to the right. The intestinal cæca are absent in the Oceanitidæ, but present, though small, in Procellariidæ. Mr. Forbes mentions and illustrates many peculiarities of the myology of these groups. The pectoralis primus is very large and divisible into two layers, as in many of the storks; the other pectorales are large, as might be anticipated from the powers of flight possessed by these birds. The biceps are small and peculiarly modified, the coracoid head alone forming the muscle proper, the humeral head going entirely to the tensor patagii longus tendon. The deltoid and glutei muscles are short and small. The tensor patagii brevis and longus are specially modified in the different species. Mr. Forbes gives a careful description of the different forms of the trachea and syrinx in the different species, the peculiarities being illustrated by many woodcuts. A short description is given of the osteology. He entirely agrees with the propriety of Professor Garrod's division of the entire order of Tubinares into two main families of Oceanitidæ and Procellariidæ, the distinctive features of which he carefully sums up. This report is illustrated by seven plates representing respectively the beak and feet, the alimentary canal, the muscles (three plates), the skull, and shoulder girdle, all excellently drawn.

The Diseases of the Prostate; their Pathology and Treatment. Comprising the Jacksonian Prize Essay for the year 1860. By Sir HENRY THOMPSON, Surgeon Extraordinary to H. M. the King of the Belgians, etc. Fifth Edition. London: J. & A. Churchill. 1883.

THE result of Sir Henry Thompson's experiment in the publication of the last edition of his *Clinical Lectures* in a cheap form has been such that when a new edition of his work on *Diseases of the Prostate* was called for, he determined to issue it in the same cheap form, at one-fourth of its former price. The work has been thoroughly revised, and the results of the author's more recent experience have been incorporated in it. The most notable addition is a chapter in which two operations for the relief of cases of Prostatic Hypertrophy, with very irritable and contracted bladder, necessitating the very frequent use of the catheter, are described. These operations are opening the bladder above the pubes, and opening into the membranous urethra in the perineum. Sir Henry Thompson now practices the latter operation, and speaks very highly of the excellent results it has yielded in his hands in this very troublesome and painful form of disease. The last chapter, on the Relation between Hypertrophied Prostate and Stone in the Bladder, is considerably modified; far less than formerly is said about the treatment of phosphatic concretions by solvents, "so greatly has the mechanical process of removing calculous matter in any form been improved." In the previous edition of 1868 Clover's bottle is described, and as the result of using it "not less than two hundred times," Sir Henry Thompson states that "it is necessary to use all such apparatus with extreme gentleness, and I prefer to do without it if possible, as its employment is quite as irritating as a sitting with the lithotrite. Repeated in-

jections, which alter rapidly and considerably the size of the bladder, are always irritating to that organ." Now (1883) we read that Bigelow's operation "has been proved the most successful operation ever practiced in dealing with very large and hard formations." It is interesting to read in the 1868 edition the following piece of advice in relation to Clover's bottle: "It is scarcely necessary to remark that before using this instrument on the living subject, it is desirable to practice with it by extracting stone or coal from a basin of water." Why has this piece of wise counsel been withdrawn from the present edition? We do not find in this cheap edition all the beautiful engravings of hypertrophied prostates that appeared in the former editions, but there are some new woodcuts which perhaps are more useful.

Politzer's Text-book of the Diseases of the Ear and Adjacent Organs. Translated and Edited by JAMES PATTERSON CASSELLS, M.D., M.R.C.S. Eng.

Diagnosis and Treatment of Ear Diseases. By ALBERT H. BUCK, M.D., Aural Surgeon to the New York Eye and Ear Infirmary.

DR. POLITZER's manual, which is a large volume of 800 pages, and illustrated by 257 wood engravings, contains not only all that is common knowledge as to ear diseases, and most of the recognized methods of treatment, but in it may be found the author's opinions upon nearly every kind of treatment that has been recommended in the recent numerous contributions to this branch of surgery. Dr. Cassells has done good service to English readers by furnishing them with so excellent a translation. Although the illustrations of the membrana tympani are altogether diagrammatic, they will be readily understood by those who are in the habit of constantly examining this structure. Nothing can exceed the clearness with which every change that can be seen in the membrane is described, and this accuracy would be expected by those who are familiar with the writings of Dr. Politzer. The anatomy of the ear, the physiology of the sound-conducting apparatus, are most thoroughly dealt with, as also are the methods of examination and the various operative measures that are in daily use with the workers on the subject. The three divisions which are now recognized in affections which implicate the lining membrane of the middle ear are separated by a very definite line—viz., catarrh in which the mucous secretion is in excess; catarrh in which there is no increased secretion (the proliferous catarrh of some authors); and those cases in which the process of inflammation proceeds to the formation of pus with rupture of the membrane. On the subject of posterior nasal catarrh the dangers that may occur from the use of the nasal douche are insisted upon, but it is now probably well known to most aural surgeons that fluid used in this way to the nostrils may pass up the Eustachian tubes and excite inflammation in the tympanum. It is, however, to the chapters on the treatment of the various forms of catarrh that the reader will turn with the greatest interest. In the simple cases where secretion is in excess Dr. Politzer relies on repeated inflation with the Politzer bag, and astringent solutions applied to the pharynx. When there is abundant evidence of secretion within the tympanic cavity he says as follows: "I perform paracentesis of the membrana tympani in those cases in which, after the application for several days of the methods of treatment already described, no decrease of the exudation is observed,

and in which, even when no exudation is demonstrable, the improvement in hearing, the immediate result of inflation, disappears again almost entirely in two or three days. I also frequently perform the operation in those cases in which at the first examination the accumulated exudation is seen to be copious. For although in these cases a cure may be effected by inflation alone, the treatment will frequently extend over several weeks, while by means of paracentesis a complete cure may be accomplished in a few days. The great advantage of this operation lies, therefore, in shortening the duration of treatment." The direction of the incision, whether vertical or horizontal, he regards as unimportant, but the length should be sufficient to ensure a free escape, for the air is of course passed through the middle ear to expel the secretion of mucus. With regard, therefore, to the propriety of making an opening for the escape of what seems a mucous accumulation, Dr. Politzer would appear to be in accord with the practice of many aural surgeons, but when he comes to discuss the question of operations on the tympanic membrane in cases of disease of the middle ear which are not attended with increased secretion, although a complete description is given of probably every kind of operation that has been suggested and practiced, the impression that will be left on the reader is that the results are discouraging in the extreme. This will apply also to the section of the posterior fold of the membrana tympani which was suggested and practiced by Dr. Politzer himself as long ago as 1871. Of this he now says, that although a temporary improvement at times took place, "only in a very small number of cases have I observed an improvement in the hearing lasting for several years, and a permanent removal or diminution of the subjective noises." Probably few have had greater opportunities than Dr. Politzer of seeing patients who have either had, or are said to have had, the tensor tympani muscle divided, and he describes at great length the operation and varieties of the instruments that have been suggested for its performance. Then, after saying that the experience which has been gained in competent quarters is on the whole unfavorable to it, he concludes as follows: "Division of the tensor tympani is, therefore, one of those operations which not only are of but trifling use, but which sometimes also have a deleterious influence upon the functions of hearing." Altogether the opinions which Dr. Politzer expresses on the vexed questions in treatment may be said to accord with those which met with general approval when these subjects were exhaustively discussed at the recent International Medical Congress, in the section for Diseases of the Ear.

The same observation may be said to apply to the views which are expressed in Dr. Buck's "Diagnosis and Treatment of Ear Diseases," except in so far as regards the frequency with which he practices paracentesis of the membrane. Dr. Buck inclines to the belief that, with patience and the ordinary method of treatment, the cases are rare in which it is desirable to make an opening in the membrane for the evacuation of mucus. He also very strongly advises the frequent application of a saturated solution of nitrate of silver to the posterior nares and pharynx when these parts are affected with catarrh. Indeed he has for some years given up the use of any other astringent in this direction, and has obtained excellent results. Although a brief mention is made of the practice of other well-known otologists, Dr. Buck's book is rather an account of his personal experiences than a detailed treatise on the subject of aural surgery. A great number of cases are well reported, and the author's large experiences make

his book extremely interesting to those whose studies are of a similar nature. On the treatment of perforations of the membrane, Dr. Buck speaks very strongly in favor of the introduction of a weak solution of nitrate of silver into the tympanic cavity through the perforation by means of middle-ear pipettes. By these instruments (slender glass tubes, fitted with a small india-rubber ball at one end) a few drops of the fluid can be injected through the perforation. Before this is done the tympanum is carefully freed from secretion and dried, and when there appears to be much inspissated pus in the tympanum this cavity is washed out before drying. Dr. Buck regards this plan of treatment as "simply invaluable." By far the most interesting and instructive part of the book is the chapter on Diseases of the Mastoid Process, in which forty-eight cases are given where inflammation has involved more or less the mastoid bone. Several of these cases terminated fatally by cerebral abscess or meningitis, and they form a most valuable clinical record. The book will be especially attractive to those of our readers who are familiar with Dr. Buck's contributions to the Transactions of the American Otological Society.

The Essentials of Bandaging. With Directions for Managing Fractures and Dislocations, for Administering Ether and Chloroform, and for Using other Surgical Apparatus; and containing a chapter on Surgical Landmarks. Illustrated by 136 Engravings on wood. By BERKELEY HILL, M.B., F.R.C.S., Surgeon to University College Hospital, etc. Fifth Edition. Revised and enlarged. London: Smith, Elder & Co. 1883.

This excellent little work is so well appreciated by students, for whom it is especially intended, that we need do little more than notice the appearance of this new edition. Mr. Hill has made no alteration in the plan of the work, although he has made some useful additions, such as an account of Thomas's splints for the treatment of the disease of the hip and knee-joints, and Carr's splint for Colles's fracture. We notice also a brief description of the mode of using the ophthalmoscope, from the pen of Professor Tweedy, and a similar account of laryngoscopy, by Dr. G. V. Poore. A few new engravings have been added. The index is very complete. We are surprised to find that Mr. Hill continues to give so prominent a place to the treatment of dislocation of the hip-joint by pulley extension, while the reduction by manipulation is dismissed in only a few words. The description of the former is enriched with several engravings, while that of the latter has not one apportioned to it. And yet any surgeon resorting to pulleys before a thorough trial of manipulation would be seriously to blame. We notice that in speaking of the use of Davy's lever Mr. Hill states that the rod is to be pressed against the ischium of the sound side as a fulcrum. Mr. Davy makes the anus his fulcrum, and we should think this to be by far the preferable plan.

Ovarian and Uterine Tumours. By T. SPENCER WELLS. London: J. & A. Churchill.

The great experience which Mr. Wells has had in operating on the subjects of ovarian tumour—an experience larger than that of any other operator—must of itself render this volume of great value. The work is a new edition of the well-known work, "Diseases of the Ovaries." Ten years have passed

since the publication of the latter, and the progress made during that period in our knowledge of the physiology, pathology, and surgery of uterine and ovarian tumours is far greater than that made during any other period of equal length; and in a work with the comprehensive title of the one before us, by an author of such wide experience, we should expect to find a full account of the progress referred to. We have stated that the work is a new edition of "Diseases of the Ovaries," and we shall point out the main points in which it differs from its predecessor. Speaking generally, the arrangement of the subjects has been considerably changed, and in many chapters the order of sequence of paragraphs has been altered. Other important alterations have been made—matter has been added and matter omitted, and the result of the experience of the author during the last ten years has been incorporated. The first chapter of the former edition, treating of the anatomy and physiology of the ovaries and their appendages, has been omitted, and its place is taken by a very brief introduction. The chapter on the pathology and classification of ovarian tumours remains almost unchanged. The only alteration in it is the addition of the conclusions arrived at by Doran and Harris with regard to the origin of ovarian cysts, together with a reference to Leopold's observations on the transplantation of embryonic tissues. With this exception no reference is made to any of the work done in this department since the publication of Dr. Wilson Fox's memoir in 1864. The works of Sinety, Rindfleisch, Waldeyer, and Malassez are entirely ignored; and we cannot help feeling surprised at such grave omissions, and at the meagre and incomplete character of the account of this important subject.

The chapter on Diagnosis and Differential Diagnosis remains much the same as in the previous edition, with the exception of the part which treats of the chemical and microscopical character of ovarian fluids. This has been rewritten, and some recent observations have been incorporated.

In Chapter V. the Rise and Progress of Ovariectomy are discussed. Here Mr. Wells gives a fuller account of his early experience than in the former edition, and traces the early progress of ovariectomy in England, the European countries, and America, and the origin of antiseptics. The time has not yet come to write the history of ovariectomy (though this chapter of the book will form a valuable contribution to the subject), for some of the actors in the early days of the operation are still living. Mr. Wells performed his first ovariectomy in 1858, eighteen years after Charles Clay had begun in Manchester, and nearly as many after Frederic Bird began in London. We do not think that justice has yet been done to these and other early operators, whose work alone rendered possible the great success of Mr. Wells.

In the chapters on the Preparation of the Patient for Ovariectomy, etc., the operation of Ovariectomy, Treatment of the Pedicle, etc., there are some new points, such as the use of pressure forceps for controlling hæmorrhage, the antiseptic method of operating and treatment of the pedicle, together with a short notice of the accidents which may happen during the operation, such as fainting, injuries to viscera, and leaving foreign bodies in the peritoneum. Fifty-two pages of the book are occupied by a table of 1000 cases operated upon by Mr. Wells. Mr. Wells, at the beginning of his career as an ovariectomist, wisely resolved to publish every case upon which he operated, for at that time the operation was not generally accepted by the profession as a legitimate undertaking; but that time has gone by, and with it the occasion for the literal performance of Mr. Wells's resolve.

The operation has for years been one of the most successful of capital operations, and the publication of the table referred to can serve no useful purpose, for the information it contains is too slight to be of any great value.

In Chapter XV., under the title Recent Extensions of Ovariectomy, Battey's operation is discussed. Although this chapter contains some sound and valuable observations, yet in the seven pages of which it consists it is impossible to do justice to Battey's operation; indeed we cannot regard this chapter even as an attempt at a scientific discussion of the subject.

The chapter on Uterine Tumours consists of the remarks on the diagnosis of ovarian tumours from fibroid tumours of the uterus which appeared in the former edition, together with additional cases in which the operation for the removal of fibroid tumours of the uterus was undertaken.

The last chapter in the book is on Partial Amputation and on Complete Excision of the Uterus, and mainly consists of notes of a case (already published) in which Mr. Wells performed the Porro-Freund operation.

We must confess to a feeling of disappointment on coming to the end of this work—a work which appeared to promise so much about ovarian and uterine tumours—for we find in it very little about uterine tumours, and but an incomplete account of ovarian tumours, while there is a good deal concerning ovariectomy and the method of its performance. The work would have been more correctly entitled, "My Experience in Ovariectomy and other Operations." As the experience of a great ovariectomist we estimate the book highly, but we cannot regard it as a scientific treatise on ovarian and uterine tumours.

Lehrbuch der vergleichenden Anatomie der Wirbelthiere.

Bearbeitet von Dr. ROBERT WIEDERSHEIM, Prof. in Freiburg. Part I, pp. 476. Jena: Gustav Fischer. 1882.

Dr. WIEDERSHEIM states in his preface that the present work has been long in preparation, that he has endeavored to give in it a good *résumé* of the present state of the knowledge we possess in comparative anatomy, and that he intends it to be used by and to be useful for the student, the zoologist, and the physician. There can be no doubt that the wide extent of the field of comparative anatomy permits few even of those who are most familiar with the subject to give a general account of the structure and morphological characters of the animal kingdom. In English, for example, we have only two works that can be considered as even approaching the modern standard of knowledge in Comparative Anatomy of Vertebrata, and embracing the information obtained by recent inquirers. One of them is Mr. Huxley's work and the other that of Mr. Mivart, though the subject is given in some detail in Gegenbaur. In Germany the great work of Bronn progresses slowly—so slowly, indeed, that a second edition of the first volume is already appearing, long before the last parts of any of the higher classes are complete. In France M. Lanessan has just commenced a work on zoology and comparative anatomy, which promises well and is profusely illustrated; but on the whole it seems right that a sound and yet comprehensive work on these subjects by a master should appear. The present volume fulfils the purposes for which it was intended by its author very well. It deals, as the title implies, with the Vertebrata alone.

The plan adopted by Professor Weidensheim in this volume is that after a short general introduction he takes up successively the integument, the

skeleton, the muscles, the electric organs, and the nervous system, in the several classes of vertebrate animals, commencing always with the fishes, and rising in the scale through amphibia, reptiles, birds, and mammals, which has the advantage of enabling the student not only to follow the organ described in its gradually increasing or varying degrees of complexity, but in addition to compare it with its embryological development.

A careful study of this work would be an extremely serviceable introduction to that of human anatomy, by giving that kind of general knowledge which would familiarize the young surgeon with the broad outlines of his future work. The book is sufficiently illustrated, and the author seems to be familiar with foreign as well as German work.

The Year-Book of Pharmacy for 1882. Edited by LOUIS SIEBOLD, F.I.C., F.C.S. London: J. & A. Churchill. 1882.

THE Year-Book of Pharmacy is of such value as a work of reference that it is with much pleasure we record the appearance of this volume. During the past twelve months considerable progress has been made in the investigation of the characters and composition of some of our most valued alkaloids. If the actual synthesis of many remains as yet unaccomplished, signs are not wanting that the day is not far distant when this problem will be solved. Ladenburgh's continued researches in connection with the mydriatic alkaloids are of considerable importance. In addition to the artificial products known as tropeines he has succeeded in producing another series of analogous bases by the action of chlorohydrines on secondary amines, and these in turn yield other basic compounds resembling natural alkaloids in their composition and properties. The number of new alkaloids thus brought within the range of possibility appears to be unlimited, and opens up a wide field both for chemical and physiological research. Another subject of considerable interest, to which reference is made in this work, is the mutual relation of certain of the opium alkaloids. It will be remembered that not long ago it was announced that Grimaux had succeeded in effecting the conversion of morphia into codeia. Doubts were subsequently thrown on the identity of the codeia thus formed with the product obtained direct from opium. These doubts are now disposed of by the researches of Dott and Hesse, whose observations fully confirm Grimaux's statements. The results of an examination of several specimens of pilocarpine indicate that this substance, as met with in commerce, is not a simple alkaloid, but a mixture of two distinct bodies, differing in characters and in physiological action. The jaborine, which is usually regarded as the impurity, may be removed by treating the nitrate with absolute alcohol. Another substance which has recently received careful investigation is chinoline, and attention is called to the fact that many specimens are impure, consisting of a mixture of several homologous bodies. This is a matter of some practical importance, for considerable risk would attend the administration of a substance containing aniline and nitrobenzol. Plugge has investigated the relative activity of aconitines from different commercial sources, and finds that Petit's nitrate of aconitia is at least eight times as strong as Merck's, and a hundred and seventy times as strong as Friedlander's. The preparations known as German aconitine are by no means of uniform strength, some of them exhibiting differences greater even than those observed between the aconitines of Merck and Petit. This points to the necessity for greater care in prescribing

ing aconitine, as the dispensing of a different preparation from that intended by the prescriber might lead to fatal results. Mr. Holmes points out that the description given in the British Pharmacopoeia is inadequate for distinguishing the root of *Aconitum napellus* from other species, that the imported roots are collected by peasants having no knowledge of botany, and that they are sold without any guarantee as to the time of collection. In his opinion the only way to secure root of good and uniform quality is to limit the official drug to home-grown aconite flowering in May and June, and gathered while the plant is in flower.

In addition to an account of these interesting researches, the volume contains a number of abstracts, notes, and formulae, together with several valuable papers read before the British Pharmaceutical Congress at Southampton in August last.

A Compend of Human Physiology. By ALBERT P. BRUBAKER, M.D., Demonstrator of Physiology in the Jefferson Medical College. pp. 133. London: Henry Kimpton. 1883.

THIS is a well-written little book, and if the plan recently adopted by the College of Surgeons, of compelling every student to pass an examination at the end of the first year of study, be ever fully carried out, such a work would prove useful as indicating the extent of information implied under the term elementary physiology, and that amount of knowledge which might be fairly expected from an intelligent student after attendance on one course of lectures, and with one year's reading. We have read through a great part of the book, and have noticed but few errors. In speaking of the effects of division of the third nerve, the author states that it produces persistent accommodation of the eye for long distances, which is correct as far as it goes, but might, we think, be better expressed by saying that its division produces loss of accommodation for near objects, the author's expression implying an active rather than a passive condition. Again, the statement that the blood in passing through the lungs loses two degrees of temperature is certainly open to question. Many good observers consider that the temperature in the left auricle is not materially lower than that in the right. On the whole, however, the facts that are given are the essential ones in each section, and would constitute a good foundation for subsequent work.

The Quarterly Journal of Microscopical Science.

Edited by RAY LANKESTER, THIRSELTON DYER, E. KLEIN, and ADAM SEDGWICK. New Series. No. XC. April. London: J. & A. Churchill.

THIS part contains the following memoirs:—1. The Anatomy and Development of *Peripatus Capensis*, by the late Francis M. Balfour, an essay which has the melancholy interest of being the last work on which this talented naturalist was engaged before his death. It has been prepared from the manuscript left by Balfour by his friends Moseley and Sedgwick, who have been greatly assisted in their labors by Miss Balfour, whose beautiful drawings illustrate many of the points in the organization of this curious myriapod, and who has materially aided the editors by her knowledge of her brother's views. 2. Klein gives an account of a Morphological Variety of *Bacillus Anthracis*, which is accompanied by a plate. Dr. Lankester appends a note on the statements made in this paper. Dr. Klein also gives a short account of a pink *Torula*. 3. Marshall Ward, of Owens

College, Victoria University, describes the characters of some of the *Saprolegniae*, which are of interest as illustrating the salmon disease. 4. Vincent Harris, of St. Bartholomew's Hospital describes a Method of Double staining nucleated Blood-corpuscles with Aniline Dyes. 5. Walter Gardiner gives the particulars of his Recent Researches on the Continuity of the Protoplasm through the Walls of Vegetable Cells. 6. Mr. J. E. Blomfield supplies a Review of Recent Researches on Spermatogenesis, chiefly those of Hermann on the Selachians, those of Renson on the Rat, and Max v. Brunn on the *Paludina*. 7. Mr. G. A. Dowdeswell gives a Note on a Minute Barb which he has recognized as existing at the extremity of the tail of the spermatozoon of the newt. 8. Mr. Ray Lankester concludes the part with a memoir on the Existence of Spengel's Olfactory Organ, and of Paired Genital Ducts in the Pearly Nautilus.

A Manual of the Minor Gynecological Operations and Appliances. By J. HALLIDAY CROOM, M.D., etc., Lecturer on Midwifery and the Diseases of Women at the School of Medicine, Edinburgh, etc. Second Edition, Revised and Enlarged. Edinburgh: E. & S. Livingstone. London: Baillière, Tindall & Cox. 1883.

WE have great pleasure in recording the fact of a second edition of this very useful and lucid little book, dealing with details in a delicate branch of practice, which are not always sufficiently given in more pretentious works. The book is larger by eighty or ninety pages than the first edition, and contains many new and beautiful illustrations. Dr. Croom modestly devised his book originally for students; but it may well be possessed by all practitioners, who will find in it carefully and briefly stated points and particulars of much utility in daily practice.

Minutes of the General Medical Council, of the Executive Committee, and of the Branch Council for the Year 1883. London: Spottiswoode & Co., Parliament-street.

OUR readers may be glad to know that the Minutes of the Medical Council for the year, including the Report of the Pharmacopoeia Committee and the suggestions of Professors Redwood, Bentley, and Atfield on the contemplated revision, and Dr. Chambers' very interesting statement on unqualified assistants, are now to be had of the publishers. Mr. Miller, with his usual aptitude for editing, has very promptly put all the materials into a little volume, with an index, not perfect, but very useful till the complete volume for the year can be had.

A Text-Book of Pathological Anatomy and Pathogenesis. By ERNST ZIEGLER, Professor of Pathological Anatomy in the University of Tübingen. Translated and edited for English Students, by DONALD MACALISTER, M.A., M.B. Part I.: General Pathological Anatomy. London: Macmillan & Co. 1883.

THIS work is a distinct acquisition to a branch of medical science that hitherto has not been well supplied by English authors, and its appearance so soon after the publication of an English edition of Cornil and Ranvier's Manual testifies to the need that is felt in this country for standard works on a rapidly advancing subject. Mr. Macalister

deserves certainly the best thanks of our students for so promptly presenting them with this, the latest, and in some respects, the best, work on Pathology at present available. In Germany its reception has been remarkable—a second edition of the first parts of the book being called for within twelve months of their appearance, and before the remaining portions have been issued. Nor, when the work is examined, can we feel surprise at the success it has achieved. For not only does it fulfil the requirements of the day in presenting students with the results of the accumulated research of past years upon pathological subjects, but it bears throughout the stamp of a thoughtful mind and an earnest worker. Invited to undertake the preparation of a new edition of Förster's well-known text-book—a work which has run through many editions, and which was itself, we believe, largely based on the classical work of Rokitsansky—Professor Ziegler found that to bring that work up to the modern standpoint would require him practically to rewrite it. He fortunately refrained from pouring new wine into an old bottle, and set himself to the task of preparing the present work, with what success we have already indicated.

At present two parts have been published, and the volume before us consists of the first of these—that which deals with general pathological anatomy. The subjects are treated in the following order—(1) Malformations, (2) anomalies in the distribution of blood and lymph, (3) retrogressive disturbances of nutrition, (4) progressive or formative disturbances of nutrition, (5) inflammation and inflammatory growths, (6) tumours, and (7) parasites, and the whole work is planned on a very definite and systematic method. There is, too, much matter introduced that is novel to similar works, showing how great have been the advances in the subject of which it treats. Thus we find included under the head of Necrosis an account of the interesting process of "coagulation necrosis," to which attention has been especially directed by Weigert and Cohnheim, and which is held to explain the formation of fibrinous false membranes; the effects on an organ of an embolic infarction, the peculiar degeneration of muscle known as Zenker's change, etc. Another section deals with the process of "colliquative necrosis," or softening. Professor Ziegler also gives prominence amongst the degenerative changes to hyaline degeneration of fibrous tissues, a change that has a superficial resemblance to amyloid degeneration without possessing its peculiar reactions. Again, in dealing with the cellular processes concerned in hypertrophy, hyperplasia, and regeneration, the author describes the remarkable structural changes undergone by cell-nuclei which were brought to light mainly by the researches of Flemming. He also devotes a short chapter to the interesting subject of metaplasia, or the conversion of one tissue into another of different type—e.g., of cartilage into mucoid or areolar tissue, or of fibrous tissue into bone.

The chapter on Inflammation deserves especial mention from the remarkably clear manner in which the author has dealt with the subject about which so many and varied views have been held. After describing the process and the varieties of inflammation, he passes to consider the later stages of the process, including repair, granulation, and cicatrization. Under the head of the "infective granulomata," Dr. Ziegler describes in turn the neoplasia characteristic of tuberculosis, syphilis, leprosy, lupus, glanders, and actinomycosis. The subject of tuberculosis is dealt with in a way which carries conviction to the reader, and it is interesting to observe how readily the idea of a specific organized virus harmonizes with the

conclusions arrived at from the purely anatomical standpoint respecting this disease. When the first edition of the work was issued Koch's discovery had not been made; but in the present volume the fact of that discovery is held to give an answer to the question of the nature of the tubercular virus, and the author says, "It may therefore be accepted as an established fact that tuberculosis is an infective disease induced by the presence of a specific bacillus." Further on, he remarks, "Clinical experience would seem to indicate that the tubercle bacillus is no ordinary bacterium, such as may enter and affect any organism without distinction. It would seem rather as if infection occurred only where a definite predisposition exists, or where a considerable quantity of the virus is introduced. This predisposition may be local as well as general. The local predisposition may perhaps depend mainly on antecedent inflammatory change. A general predisposition is attributed to *scrofulous* subjects especially. These are persons whose tissues exhibit a certain frailty or susceptibility to injury that makes them particularly liable to chronic inflammatory disorders. It is, however, not at all uncommon for the term '*scrofulous*' to be applied to individuals actually affected with tuberculosis, as well as those who are only predisposed to it." It might be thought that this unreserved adoption of so recent a discovery and the wide deductions that flow from it should hardly have found place in a text-book, where only facts that are well established and likely to be permanent should be quoted. But, to our mind, the very fact that so much prominence is given to it by the author is an admission of the thoroughness and exactitude shown by Koch in all his work, whilst the discovery of the bacillus has only crowned the edifice which pathologists have been slowly and painfully laboring to raise. When the history of this chapter of pathological research comes to be written, no fact will come out more clearly than this, that the anatomical study of tubercular lesions forced upon the mind the idea of a virus which by analogy from other diseases was supposed to be of bacterial nature. No one can foretell how far the knowledge gained concerning the influence of micro-organisms upon morbid processes will have led pathologists fifty years hence, or what further changes may be wrought in the pathological conception of tuberculosis. We may be sure of this, that the doctrine of its specific and infective nature, first initiated by Virchow, but widely extended and modified by his followers, will remain unshaken.

The sections upon Tumours does not deal so minutely with them as the chapters in Cornil and Ranvier's work, but it is ample enough and thoroughly represents the standpoint arrived at by modern histological research. This section concludes with a very interesting discussion of the etiology of tumours, in which Cohnheim's speculations of embryonic "residues" are justly held to be inapplicable to the explanation of many forms of new growth. The structural affinities of new growths are now fairly well known; but what is required, and what future observers will be bound to investigate, is their mode of origin and evolution. This is a difficult field, and one in which clinical rather than experimental research may furnish most material.

The concluding section on Parasites is notable for the very full account given of the bacteria. It is the first time that a text-book has ventured upon this intricate and ever-spreading department of pathology, and certainly the author has managed to survey the whole field of facts respecting pathogenic micro-organisms in a masterly manner. Teachers, as much as students, will be

glad to have before them a work which contains not only so accurate an account of these micro-organisms, but such ample references to the literature of the subject.

We must not conclude this notice without calling attention to the number and excellence of the illustrations, the large majority of which are original; nor without a word of commendation to Mr. Macalister for his able rendering of the work, which is certain to be widely read in this country.

Medical Annotations.

"Ne quid nimis."

MR. WATSON CHEYNE'S RESEARCH ON TUBERCULOSIS.

THE first fruits of the newly formed Association for the Advancement of Medicine by Research consist of Mr. Watson Cheyne's investigation into the relations of micro-organisms to tuberculosis; and his report of the inquiry, presented to the Association, was published by us last month. Space will not permit us to analyze this report as fully as it deserves, but occasion will doubtless often arise for further reference to it, as it seems to be a most important contribution to the subject. Mr. Cheyne tells us that he visited the laboratories of Professor Toussaint at Toulouse and Dr. Koch at Berlin, so as to become acquainted with their experiments and to obtain the material employed by them. As to his own work, he first of all cleared the ground considerably by demonstrating that tuberculosis cannot be excited in rodents by simple irritants, or even by Toussaint's micrococci, when full precautions were taken to prevent contamination from tubercular virus; and he further thoroughly confirms Koch in the conclusion that the infectivity of tuberculous material depends upon the presence of the tubercle bacilli. He always found these bacilli in specimens of tuberculous material, but in varying amount, and noted their greater abundance in bovine than in human tuberculosis. In pursuing the inquiry further—as to the relation which these organisms bear to the morbid processes in man—he points out the complete identity between acute tuberculosis in the human subject and in the lower animals, but admits the greater difficulty there is in understanding the relation of the bacilli to the localized tuberculous processes in man; with only one of which, viz., phthisis, he deals in the present report. His description of the phthisical process and of the share taken in it by the bacilli is very convincing. The bacilli were found most abundantly in the epithelioid cells, which apparently play a very important part in pulmonary tuberculosis; the giant-cell formation is derived from these epithelioid elements, which themselves are derivatives of the alveolar epithelium mainly (and occasionally of the epithelia of the bloodvessels and lymphatics), whilst the granulation-celled structure is regarded as due to surrounding inflammation. In this fact of the constant presence of the bacilli in such formations as contain these epithelioid cells, we have a suggestive point capable of application to tuberculosis of other organs than the lungs. Mr. Cheyne contrasts the two extreme conditions of phthisis—the acute caseous pneumonic form and the chronic fibroid form—finding, in confirmation of statements made from examination of the sputa by others, that the bacilli are extremely scanty in the latter but abundant in the former; and he suggests that the

difference between these types of consumption probably depends "on the number and growth of the bacilli, and on whether the patient is a good soil for their development." But these and other points are no doubt amply argued in the complete report shortly to be published. In the present abstract, Mr. Watson Cheyne states sufficient to show that his researches throw new light upon a subject which will afford for some time to come a rich field for investigation, with a promise of results of the highest importance to mankind.

THE AIM OF EXERCISE.

It should be understood by the public, as it is known to the profession, that the aim of exercise is not solely to *work* the organism which is thrown into activity, though that is one, and a very important, part of the object in view, because as the living body works it feeds, and as it feeds it is replenished; but there is another purpose in exercise, and that is to call into action and stimulate the *faculty of recuperation*. Those who believe in the existence of a special system, or series, of trophic nerves, will not object to this designation of the recuperative function as a separate "faculty," and those who believe nutrition to be effected in and by the ordinary innervation will recognize the sense in which we employ the term in italics. It is through defect or deficiency in the vigor of this faculty, unaccustomed feats of strength, whether of mind or muscle, are found to be exhausting. The task is performed, but the underlying faculty of restorative energy, or power of recuperative nutrition, located in the particular part exceptionally exercised, is not in a condition to respond to the unusual call made upon it. When a man goes into training, or, which is practically the same thing, when he habituates himself to the performance of a special class of work, he so develops this recuperative power or function that the repair or replenishing necessary to restore the integrity, and replace the strength of the tissue "used up" in the exercise, is instantly performed. The difference between being accustomed to exercise and able to work "without feeling it," and being barely able to accomplish a special task, and having it "taken out" of one by the exploit, whether mental or physical, is the difference between possessing the power of rapid repair by nutrition, and not having that power in working order—so that some time must elapse before recovery takes place, and during the interval there will be "fatigue" and more or less exhaustion. The practical value of a recognition of this commonplace fact in physiology will be found in the guidance it affords as to the best and most direct way of developing the power or faculty of recuperation by exercise. Many persons make the mistake of doing too much. Exercise with a view to recuperation should never so much exceed the capacity of the recuperative faculty as to prostrate the nervous energy. The work done ought not to produce any great sense of fatigue. If "exhaustion" be experienced, the exercise has been excessive in amount. The best plan to pursue is to begin with a very moderate amount of work, continued during a brief period, and to make the length of the interval between the cessation of exercise and the recovery of a feeling of "freshness" the guide as to the increase of exercise. We do not mean that false sense of revival which is sometimes derived from the recourse to stimulants, but genuine recovery after a brief period of rest and the use of plain nutritious food. If this very simple rule were carried into practice by those who desire "to grow strong," there would

be less disappointment, and a generally better result, than often attends the endeavor to profit by exercise unintelligently employed.

PROTECTIVE INOCULATION—KOCH AND PASTEUR.

THE controversy which has arisen between the two foremost investigators into the intimate nature of contagion—the veteran chemist of Paris, and the younger pathologist of Berlin—is one of which we are only just seeing the commencement. The issues are so important, that it is to be desired that renewed investigation will be undertaken by unprejudiced observers, in the hope that the truth may be revealed. There can be no denying that Dr. Koch has hit the weak points of M. Pasteur's case, and his analysis is all the more vulnerable from the severe and critical manner in which he has dealt with the subject—a style which differs very widely from that of his opponent—a difference partly, no doubt, explained by the admitted diversity in modes of thought, work, and expression between the Gaul and the Teuton. Those who have perused the summary of Dr. Koch's reply, that we have just published, will note how little agreement there is between himself and M. Pasteur, not only upon the subject of anthrax, but upon those other infectious diseases which have been experimentally studied by the latter. Thus Koch thinks it indubitably proved that the supposed virus of rabies which Pasteur discovered is identical with that of the septicæmia of rabbits; and he says the same of equine typhoid too, thereby implying that M. Pasteur is ignorant of the characteristic microbe of septicæmia in rabbits, or that he has been very careless in safeguarding his observations. Indeed, Koch's strongest attack is directed against the method followed by Pasteur in his assumption of a specific micro-organism in the saliva of a hydrophobic child, or in the nasal mucous of a horse suffering from typhoid fever, without taking the precaution to isolate the organism and cultivate it before making his inoculations—the method which Koch claims to be the only safe one for determining the question. It is in anthrax that the most important issues are involved, for it is only in this disease that the practical application of Pasteur's doctrine has been made—viz., that immunity from this scourge can be attained by vaccinating (or rather inoculating) sheep and oxen with the attenuated virus. Koch admits the fact of attenuation, and it may be remarked, agrees with Pasteur and differs from Dr. Klein, in believing that this is due to some change effected in the pathogenic bacilli themselves; but he does not admit that this change is due to the oxygen of the atmosphere, as M. Pasteur thinks, and by a series of carefully conducted experiments he shows how the virus loses its power in cultivation more or less rapidly according to the temperature to which it is submitted. There are graver differences than this, however, which may be summed up in a very few words. The method of vaccination is alleged by Koch to be imperfect. Although an animal previously inoculated with a highly attenuated virus is able to resist the effect of a second and more powerful vaccination, yet this is not a universal rule, and a certain proportion of the vaccinated animals—a number which Koch places much higher than Pasteur—die from the effects of the secondary vaccination itself. After passing through so severe an ordeal, the survivors should be sufficiently protected, if any real practical value is to accrue from the method. But Koch shows that, although they may resist further inoculations, such animals may still fall victims to spontaneous anthrax. If this be true, where is the protection? and what reli-

ance is to be placed upon the "vaccinations" and "revaccinations" to which so many thousand head of cattle in France and elsewhere have been subjected? Coming from one whose researches upon this and other infectious diseases have received general approbation for the exactitude and care with which they are conducted, such criticisms as are here offered upon Pasteur's labors must receive attention; for it must never be forgotten that, wide apparently as is the principle upon which Pasteur has based his advocacy for "vaccinations," applicable as it may seem to be to many human diseases, it has yet to be conclusively proved, even in the case of anthrax, where the conditions and nature of the virus have been so thoroughly worked out.

FILARIA DISEASE.

THE rapid strides which our knowledge has made during the past few years in the subject of the filaria parasite have been mainly owing to the diligent researches of Dr. Patrick Manson, who continues to work at the question. In the last number of the Medical Reports for China Dr. Manson deals with the phenomenon known as "filarial periodicity," and with the fate of embryo parasites not removed from the blood. The intimate pathology of the disease, and the subject of abscess caused by the death of the parent filaria, also receive further attention. An endeavor to explain the phenomenon of "filarial periodicity" by an appeal to the logical "method of concomitant variations" takes Manson into an interesting excursion which is not productive of any positive results; nor is any more certain conclusion come to with regard to the fate of the embryos which disappear from the blood during the day-time. Manson does not incline to the view that there is a diurnal intermittent reproduction of embryos with a corresponding destruction. An original and important speculation is made with respect to the intimate pathology of elephantiasis, chyluria, and lymph scrotum, which is thoroughly worthy of consideration. Our readers are probably aware that the parent filaria and the filaria sanguinis hominis may exist in the human body without entailing any apparent disturbance. The diameter of an embryo filaria is about the same as that of a red blood-disc, 1-3000th of an inch. The dimensions of an ovum are 1-750th by 1-500th of an inch. If we imagine the parent filaria located in a distal lymphatic vessel to abort and give birth to ova instead of embryos, it may be understood that the ova might be unable to pass such narrow passages as the embryo could, and this is really the hypothesis which Manson has put forward on the strength of observations made on two cases. The true pathology of the elephantoid diseases may thus be briefly summarized: A parent filaria in a distal lymphatic prematurely expels her ova; these act as emboli to the nearest lymphatic glands, whence ensue stasis of lymph, regurgitation of lymph, and partial compensation by anastomoses of lymphatic vessels; this brings about hypertrophy of tissues, and may go on to lymphorrhœa or chyluria, according to the site of the obstructed lymphatics. It may be objected that too much is assumed in supposing that the parent worm is liable to miscarry. But as Manson had sufficient evidence in two cases that such abortions had happened, he thinks it is not too much to expect their more frequent occurrence. The explanation given of the manner in which elephantoid disease is produced applies to most, if not all, diseases, with one exception, which result from the presence of the parasite in the human body. The death of the parent parasite in the afferent lymphatic may give

rise to an abscess, and the frequency with which abscess of the scrotum or thigh is met with in Chinese practice is, in Manson's opinion, attributable to this. Dr. Manson's report closes with an account of a case of abscess of the thigh, with varicose inguinal glands, in which fragments of a mature worm were discovered in the contents of the abscess.

DEATH FROM FRIGHT.

ON a recent occasion we commented on the physiological causes of death from fear. A curious instance of this description of casualty has just occurred. A child seven years old, the son of a sweep, and therefore not likely to have been brought up during the few years of his little life too tenderly, fell down and died from fright at seeing two older boys fighting. There is said to have been no organic disease discernible on post-mortem examination. This is remarkable, but it is, of course, possible that the impression made on the brain of this child may have been so strong as to arrest his heart's action. We confess we should like to hear more of the case in its strictly medical aspect. Meanwhile there can be no hesitation in pronouncing a strong opinion against the exposure of young children to powerfully affecting and more particularly terrifying spectacles. The practice of "frightening" children either to quiet them or simply as a diversion is inhuman in the extreme. Many cases of epilepsy have had this sort of agency for their exciting cause. It is a cruel and heartless pastime in which too many otherwise kindly intentioned persons are wont to indulge.

ACCESSORY SUPRARENALS.

PHYTOGENESIS has been said to be the mechanical cause of ontogenesis. The development of the individual is the compressed development of the race. No doubt in the process of compression some features are suppressed, whilst others are thrown into relief, but even these characteristics may be capable of a good explanation. The light which comparative embryology may be able to throw on many questions of present obscurity may turn out to be not inconsiderable. In the *Quarterly Journal of Microscopical Science* for 1882, the lamented Balfour has contributed a paper on the Development of the Suprarenal Bodies in Mammalia, which is full of suggestiveness from an embryological standpoint. There seems to be no reasonable doubt that the cortical and central parts of the adrenal of higher animals are as widely different in their nature as any two tissues can well be. The Elasmobranch fishes possess a single organ of inter-renal situation, which in structure corresponds with the cortical portion of a mammalian suprarenal body; here there is a local and actual separation between the two constituents which supports the notion of their essential difference. In fact the medullary part of the suprarenal body is in intimate relation with the sympathetic ganglia of the abdomen, and may be regarded as a part of that neural chain. And this is a view which all pathological researches tend to support. The vital opposition of these two tissues of the adrenals becomes an almost indispensable feature for the maintenance of the notion that the accessory bodies found by Dr. Marchland in the broad ligament of the uterus, are really of the nature of suprarenal bodies. The observations were made on infants either new-born or only a few months old. The bodies in question were always quite small, from one to three millimetres in diameter, of rounded shape and yellowish color. In four cases the nodules were situated at the free

end of the broad ligament, in immediate relation with the ovaries, and consequently in close association with the pampiniform plexus from which the ovarian vein starts. They are thus enclosed between the two laminae of this peritoneal fold, and project more from the anterior than from the posterior aspect. One instance is given of their occurrence nearer to the body of the uterus. A case is mentioned where the accessory nodules were located one on each side below the kidneys, in near relation with the ovarian vein. Rokitsansky has described these accessory adrenals in a position between the solar and renal sympathetic plexuses, and sometimes a large part of the suprarenal organ has been found to be spread out beneath the capsule of the kidney. The explanation offered by Marchland in Virchow's *Archiv* is that the additional adrenals are probably carried down to the broad ligament with, or in connection with, the ovarian vein. Similar structures have not been found in the male, though their presence in some part of the course of the spermatic vein is not impossible.

SHOULD WOMEN RIDE LIKE MEN?

SUCH is the question which is being seriously discussed in the columns of a contemporary. Perhaps it would be as well to leave the determination of the question to those whom it principally concerns. We fancy they have no wish to change the custom. As a matter of fact, although it may not appear to be the case, the seat which a woman enjoys on a side-saddle is fully as secure, and not nearly as irksome, as that which a man has to maintain, unless he simply balances himself and does not grip the sides of his horse either with the knee or the side of the leg. It is curious to note the different ways in which the legs of men who pass much time in the saddle are affected. Riding with a straight leg and a long stirrup almost invariably produces what are popularly called knocked-knees. Nearly all the mounted soldiers of the British army suffer from this deformity, as anyone who will take the trouble to notice the men of the Life Guards and Blues walking may satisfy himself. On the other hand, riding with a short stirrup produces bowed-legs. Jockeys, grooms, and most hunting men who ride very frequently are more or less bow-legged. The long stirrup rider grips his horse with the knee, while the short stirrup rider grips him with the inner side of the leg below the knee. This difference of action explains the difference of result. No deformity necessarily follows the use of the side-saddle if the precaution be taken with growing girls to change sides on alternate days, riding on the left side one day and the right on the next. The purpose of this change is to counteract the tendency to lean over to the side opposite that on which the leg is swung.

WOMEN'S DRESS.

THAT monstrosity of fashion, "the divided skirt," calls for criticism chiefly because it is so persistently obtruded on public attention as to bid fair to become a nuisance. If women please to unsex themselves in dress as well as in habits of life and silly exploits of possible, but not prudent, intellectual and physical energy, they may be left to compass their own discomfort without more than an ordinary warning; but when they appeal to the canons of health in support or defence of their vagaries, it is necessary to show that the appeal is inadmissible. The divided skirt is clearly not likely to advance the interests or improve the health of the sex if it should be commonly adopted as the dress of the period. It is unnatural, and

must be productive of unwomanly ways which are to be deprecated. Moreover, as it approaches the trousers in form and use it must tend—despite of projected reduction in the amount of under-clothing—to increase the heat of the limbs and body in a way which is undesirable. In short, the divided skirt is an outrage, and not to be countenanced. Meanwhile, the disuse of corsets is undoubtedly expedient; whether these casings be tight as well as stiff, or only the latter, they must necessarily restrain the movements of the thorax, and thrust down the abdominal viscera in a manner which is decidedly injurious; The attempt to substitute shoulder-straps for waistbands as clothes' suspenders is also good as far as it goes; but it would be well to reduce the weight to be carried by half or two-thirds. Surely women have no idea of the burden they bear. No wonder they are weak and unable to take sufficient bodily exercise. Twenty to five-and-twenty pounds weight is not, we believe, an exaggerated total for the burden of dress borne by a fashionable lady fully equipped for a promenade in chilly weather, when a mantle or "Dolman" has to be worn. There is abundant room for reform in female dress, though we do not think it desirable that the changes made should be precisely those just now contemplated—in certain quarters at least.

ADDISON'S DISEASE.

THE latest contribution to the above subject consists in a concise essay by Dr. Burger, of Bonn ("Die Nebennieren und der Morbus Addisonii," Berlin, Hirschwald), in which an inquiry based upon the chief literature on the subject is made into the assumed connection between disease of the suprarenal capsules and the phenomena of Addison's disease. The anatomy, physiology, and morbid anatomy of the adrenals are first discussed, and then follows an exact description of Addison's disease, concluding with a review of the facts and arguments which point to the abdominal sympathetic as the source of its symptoms. The writer sums up as follows: That structurally the adrenals should be classed with the blood-vascular glands, and they are not necessary for life. They have no connection with the cutaneous bronzing of Morbus Addisonii; a pigmentation which is not peculiar to that affection, since it may be present in very different forms of cachexia. Diseases of the adrenals are not uncommon, and they very often run their course without producing the phenomena of Addison's disease. In Addison's disease the most varied forms of adrenal affection may occur; but when supra-renal disease is present it does not contribute to the symptoms of Addison's disease, which depends upon an affection of the semilunar ganglia and solar plexus. This nerve change is generally brought about by disease of the supra-renals, the most frequent form of which is tuberculous inflammation. But the affection of the semilunar ganglia and solar plexus may be equally induced by disease of other organs, and may further arise spontaneously, so that the symptoms of Addison's disease may be produced apart from any change in the supra-renal capsules. In the main these results are consonant with our present knowledge of the pathogeny of this remarkable disease; the point which seems most open to question being that many kinds of morbid change of the supra-renal capsules may be found associated with Addison's disease. We had thought that evidence was overwhelming in support of the fact that when supra-renal disease is present it is of the kind which the writer admits to be most frequent—viz., a form of tuberculous inflammation.

SENSE-CULTURE.

THE special culture of the senses is too much neglected by us in this modern busy life. Probably at no previous period of human history has the nervous system generally, and, more particularly, have the sense-organs been so severely taxed as they now are, but never have they been less carefully cultivated. This is in part, if not wholly, the cause of the progressive degeneracy of the faculties of special-sense which is evidenced by the increasing frequency of the recourse to spectacles, ear-trumpets, and the like apparatus, designed to aid the sense-organs. The mere use of faculties will not develop strength—it is more likely to exhaust energy. Special training is required, and this essential element of education is wholly neglected in our schools, with the result we daily witness—namely, early weakness or defect in the organs by which the consciousness is brought into relation with the outer world. It is not necessary to adduce proofs of the position we take up, or to argue it at length or in detail. The truth of the proposition laid down is self-evident. On the one hand we see the neglect of training, and on the other the increasing defect of sense-power. The matter is well worthy of the attention of the professional educators of youth. Muscular exercise wisely regulated and apportioned to the bodily strength is felt to be a part of education. Sense-culture, by appropriate exercises in seeing, hearing, touching, smelling, would, if commenced sufficiently early in life, not merely prevent weakness of sight, deafness, loss of the sense of feeling, and impairment of the sense of smell, long before old age; but by its reflected influence on the nutrition of the brain and upper portion of the spinal cord, would do much to reduce the growing tendency to paralytic diseases, which are very decidedly on the increase.

CARCINO-SARCOMA OF UTERUS IN A CHILD.

THE most favorable time for the appearance of almost any disease of almost any organ is decidedly at or about the period of its greatest activity. But there are many exceptions. The pathological anatomist certainly does not expect to find disease of the generative organs in very young children, and past experience gives very good grounds for this expectation. Unquestionably, however, these organs are at times, though rarely, the site of well-marked disease in young children. Professor Rosenstein has recorded an example of alleged mixed sarcoma and carcinoma of the uterus in a child two years old. The child was taken to the doctor chiefly because it had not passed water for three days. On clinical examination a tumour of the belly was detected, which was partly due to a distended bladder. After 700 cubic centimetres of urine had been drawn off by means of a catheter, a tumour was still to be felt which reached about three fingers' breadth above the pubic symphysis. The child died after it had been under observation for fourteen days. At the post-mortem examination the uterus was found to be closely adherent to the bladder, an irregularly rounded tumour was seen projecting above the apex of the bladder, and apparently springing from the right lateral wall of the uterus, which was tilted towards the left; this nodule extended for about an inch beyond the limits of the fundus. Another nodule the size of a walnut was seen to project from the left of the fundus. The greatest length of the uterus was about two inches and a half, its thickness, from before back, about one inch and a half. Microscopical examination showed in some places, between the bundles of muscular tissue, a very fine alveolar stroma, packed with epithelioid cells of

various shapes and sizes, and which contained one or more nuclei. In other parts the structure resembled that of a spindle-celled sarcoma.

"CONSTIPATION" OF NERVOUS ORIGIN.

THERE are many diverse forms or causes of this malady—or abnormality of function—which it is important to recognize, but which are too commonly confounded, with the inevitable result of failure in the precise direction of remedies. The following may be noted as two or three of the commonest varieties of the trouble. For example, defect of muscular movement may be the cause of inaction of the bowels. This may be either want of peristaltic action in the small intestines or of extrusive force in the muscles concerned in the act of defecation; the location of the inertia being determinable by the character of the fæces, and the period and manner of their defection. The characteristics of fæces recently discharged from the small intestines and rapidly passed through the large intestine are too familiar to call for description. The scybalous dejecta of long retained fæces are equally well known. The error—if error there be—which is made in practice relates to the neglect of such lessons as the characteristics of the fæces are intended to teach, in regard to the cause or form of the "constipation." We lay great stress on this matter in diarrhoea, but it is practically disregarded in constipation, whereas, if possible, the character of the dejecta is more suggestive as an indication of the place and cause of detention than as an indication of the nature and cause of excessive or too rapid discharge. It is, for obvious physiological reasons, of the highest moment to determine whether constipation be due to inactivity of the muscular coats of the intestine, or of the levator ani and accessory muscles concerned in the act of evacuation. Second, there may be, and, often is, instead of inactivity, irritability of certain muscles as a cause of constipation. In a considerable proportion of cases of constipation with loaded rectum, the actual cause of the retention of the fæces is spasmodic contraction of the sphincter, which occurs the moment the levator ani begins to act. Only a little of the watery portion of the contents of the bowel escapes, the scybalous mass being retained. In cases of this class there is apt to be considerable disturbance of the pelvic viscera and other discharges while at stool. The cause of these muscular troubles is of course located in the nervous system. Sometimes the reflex excitability which should respond to the presence of fæces at particular parts of the intestinal canal is abnormally depressed, as in the constipation which arises from certain tabetic forms of spinal disease. In others the reflex irritability is unduly exalted, as in the cases of spasmodic contraction of the sphincter of which we have spoken. This increased excitability in the lower part of the cord is common, and it is generally to spasmodic irritability of the sphincter those forms of constipation are due in which the use of tobacco affords temporary relief, and seems to produce an action. As a rule it may be assumed that "habitual constipation" is an affection the cause of which must be sought in spinal exhaustion or irritability, or the two states combined. In another group of cases the cause of constipation is inactivity of the secreting glands of the intestines, from defect of innervation. We are not speaking of the cases in which the larger viscera, such as the liver, may be at fault, but of a multitude of instances in which the glandular system and apparatus of the walls of the intestinal canal are not in such a state of erectile and functional activity as to maintain the reflex excitability of the parts, and to so lubricate the

contents of the canal as to pass them rapidly along its course. This is one of the causes of that broken earth-like type of dejecta which attends a form of constipation common among subjects of spare and shrivelled physique, who are insensitive to most external impressions, though, perhaps, preternaturally sensitive to some special excitants. It is not within the scope of our purpose to discuss this topic in detail, but it is one to which the attention of the profession might be usefully directed. The practice of treating "habitual constipation" by cathartics is almost played out, and it is time the study of this common and most intractable affection from the standpoint of nervous origin and causation, should be seriously and earnestly undertaken.

THE TUBERCLE BACILLUS.

A PAINSTAKING and valuable contribution to the pathology of tuberculosis has recently been read before the Academy of Medicine by MM. Cornil and Babes. In general terms the conclusions aimed at by these histologists may be said to harmonize completely with all the teachings of Koch. Descriptions, illustrated by drawings representing the disposition and topography of the bacilli stained after Ehrlich's method in the tubercles of the meninges, serous membranes, mucous membranes, lungs, lymphatic glands, spleen, liver, and urinary organs, were forthcoming. Experimental inoculation with the sputa from cases of phthisis which contained bacilli into the peritoneal cavities of guinea-pigs gave rise, after five or six weeks, to an abundant crop of miliary tubercles in the spleen, liver, peritoneum, intestines, mesentery, genital organs, lungs, and lymphatic glands; these miliary bodies also abounded in bacteria. MM. Cornil and Babes have also searched for the bacilli in a series of lesions which, rightly or wrongly, may be regarded as intermediate between tuberculosis and scrofulosis. The characteristic micro-organisms were demonstrated in two out of three examples of scrofulous glands of the neck, taken from different individuals presenting no other obvious disease. The organisms were seen in small numbers, and only in the giant cells. The gland that was found wanting was the seat of much fibroid induration. No bacilli were discovered in a "tuberculous" abscess of the breast, nor in two cases of "tuberculous" abscess of the skin. Of three cases of *tumor albus* the bacilli were detected in but one instance, then in great scarcity, and exclusively in the centre of giant cells. Negative results were also the outcome of examinations of fragments of caseous pneumonia, interstitial pneumonia, fibroid pleura, and caseous pneumonia with vomica, in a syphilitic patient. Altogether, forty histological investigations were carried out, and M. Cornil is of opinion that from a point of view of bacilli a division into three classes may be made. In the first class would be placed all those instances in which the number of bacilli was considerable enough to explain the appearance of the tubercular lesions, just as it is supposed the nodules of leprosy may be accounted for by the growth of bacteria—in fact, an example of a genuine parasitic affection. The spread of the micro-organisms by way of the blood and lymph channels is believed to be proved by the presence of the bacilli in the interior of and about the vessels. The bacilli in the second series are not numerous, but they always exist in the midst of the tubercular lesion; this fact of central existence is regarded as sufficient to permit a belief in the notion that here, too, the affection is essentially a mycosis. The last division contains those examples of the chronic form of the disease in which the bacteria

are found only in the tissues which bound cavities and caseous material. In order to bring these cases into harmony with the prevailing views, it may be supposed that when the number of bacilli is far from being able to explain the lesions observed, there has been an elimination or destruction of bacilli, but not before they have had time to set certain inflammatory processes in action. The arrangement of the organisms in ancient tuberculous depôts may be explained by taking into account the action of the leucocytes in transporting the bacilli, and by bearing in mind that a constant elimination probably goes on when much expectoration occurs from the lungs, or when the débris of ulceration are carried off by means of the stools and the water.

COATING PILLS.

PRESCRIBERS who order pills to be coated would do well to try the experiment of dissolving a pill in a bag of slightly acidulated fluid at the temperature of nearly 100° F., and even frequently agitated. In a majority of instances it will be found that the mass is barely approached by the fluid after many hours, and does not actually break down until a very considerable period has elapsed. The obvious inference from these results must be that pills coated with gold, silver, and even mastic—unless quite recent—are not brought into a condition in which the drugs of which they are composed could be appropriated by the stomach until long after the time of administration. Again, and this is very important, it may happen that before one pill is dissolved, another may be reduced, and thus two doses of a potent drug may be possibly taken at once.

BURIAL.

THERE can, we think, be no question that the practice of burial, in the ordinary sense, must survive the impracticable device of cremation. Burning the dead is a simply revolting and socially unsafe procedure. It offends the feeling of human respect, and it would open the way for the commission of the worst crimes. Murder by poison would, in fact, be a perfectly facile way of "removing" enemies or victims if cremation were legalized. The law cannot sanction this mode of disposal of the dead, and, obviously, no man should allow the body of a friend or relative to be cremated unless the law of the land in which he lives and the State of which he is a subject permits the practice.

LIGATURE OF THE INNOMINATE.

MR. MITCHELL BANKS tied the innominate artery on Feb. 28th at the Liverpool Royal Infirmary for aneurism of the second portion of the subclavian. A ligature was also placed on the common carotid. Mr. Girdlestone's kangaroo tendons were used with strict antiseptic precautions. The patient recovered rapidly from the operation, and has already left the infirmary, with his aneurism much improved. Mr. Banks will doubtless furnish the profession with full particulars of this case.

EXTIRPATION OF THE UTERUS.

THE *Gazzetta degli Ospitali* (March 7th) reports a successful operation for the removal of the uterus per vaginam, performed by Professor Calderini, of Parma, on January 16th. The patient, a woman, aged forty-three, had suffered for two years from epithelioma of the womb, which had extended to the upper part of the vagina. This affected part

was removed, as well as the uterus, without any complication at the time of operation, or subsequent to it. The patient left her bed at the end of three weeks, and was in good health when presented to the Obstetric Institute of Parma, thirty-three days after the operation.

THE ANTIQUITY OF SYPHILIS.

THE very curious and interesting question of the origin of syphilis is one which has been keenly argued by many authorities. Perhaps the majority incline to the belief that syphilis was introduced into Europe, or originated there *de novo*, towards the end of the fifteenth century. Dr. Scheube (in Virchow's *Archiv*) contends for the antiquity of the disease. He founds his contention on the existence of a medical work of Japanese origin, written in the beginning of the ninth century. If we may trust the interpretation of the translation of that work, it would certainly seem that these ancient Japanese were sometimes the victims of a venereal disease, not one whit less loathsome or less searching than syphilis. But having gone so far, we may well ask—Was it syphilis? Was it the same disease with the dire effects of which we are still too familiar? And questions might be postulated without number, and without our ever being able to get any nearer to the truth.

AMPUTATION BY THE "COAT-SLEEVE" METHOD.

MR. KENDAL FRANKS, of the Adelaide Hospital, Dublin, on the 15th of March, removed the thigh, about the middle third, of a girl, aged seventeen, who was suffering from abscess of the knee-joint and necrosis of the tibia, by this method. A circular incision having been made through the skin and fascia, the part was dissected back for three or four inches, and, an incision having been made through the muscles down to the bone, the latter was sawn. The circular skin flap being brought down, was tied below the stump with a piece of tape, and two drainage-tubes left in the centre. The result so far is satisfactory, the patient going on favorably.

Correspondence.

"Audi alteram partem."

CURIOUS CASE OF VEGETABLE POISONING.

To the Editor of THE LANCET.

SIR—At 10 p.m. on April 11th my assistant was called to W. R.—, aged thirty. The patient was seated on a bench in his workshop with closed eyes, and apparently he was quite indifferent to all surroundings. All efforts to rouse him were unavailing, either to make him speak or in any way to answer questions. When left to himself he exhibited a slight occasional jerk of the limbs, especially of his arms. At times he made sudden thrusts into the air, as though attempting to catch flies. The pulse was rather weak, and the breathing quiet and regular; tongue moist. He obstinately prevented an examination of the pupils, and even when held by three men successfully resisted every effort to make him swallow a draught. After a cold douche to the head he talked irrationally, but soon became quiet again on being left undisturbed. There being no indication of danger, he was left in charge of his friends, after a continuous watching of nearly three hours. He was taken

home in a cab about 2 A.M. of April 12th. He had no illusions of vision whilst travelling the two miles, but on getting into his warm bedroom, he subsequently stated, he distinctly saw some one lying in his bed. At 7 A.M. of the 12th he came as usual to his workshop, when, he averred, he noticed some women sitting in his way, and that they vanished when he proceeded to turn them out. At 5 P.M. of the same day he presented himself at my surgery, and only complained of feeling "nervous," and rather sore from the rough handling of the preceding night. My assistant was informed that four hours previous to his visit on April 11th the patient had taken nearly a pint of stinging nettle "tea" made from about half an ounce of the dried herb. He had taken similar doses twice a week for some months past without any ill effects. On this last occasion a fellow workman had swallowed about a wineglassful from the said pint of "tea," and an hour and a half afterwards he also complained of dizziness and double vision, which symptoms, however, entirely disappeared after the operation of an emetic. The illusions of vision in this case came on soon after swallowing the "tea." They consisted in his seeing three or four objects where one only was present; he also saw frogs and other things crawling about, and his chief desire and endeavors were to catch them. Everything appeared green to him.

The bundle of herbs which was said to have been infused has been very carefully examined both by myself and by others, and only specimens of the common nettle (*Urtica dioica*) and of *U. urens* could be detected amongst the stems and leaves. These urticaceæ are chiefly and popularly known from their venomous sting when applied externally. The effects of some of the foreign species of the genus are recorded as dangerous. Lindley quotes M. Leschenault ("Mém. Mus." vi., 362) as describing the serious effects upon himself and a workman of gathering *U. crenulata* in the Botanic Garden at Calcutta, and the less violent effects of another dangerous species (*U. stimulans*) he found in Java. Lindley concludes: "Both these seem to be surpassed in virulence by a nettle called *Daoun setan*, or devil's leaf, in Timor, the effects of which are said by the natives to last for a year, and even to cause death." I can find no recorded evidence of any species, British or foreign, of the genus *urtica*, when taken internally, producing poisonous symptoms. I have procured of the herbalist from whom the dried herbs were bought a further supply, which he assured me he took from the same bundle whence came the former specimen he had sold to W. R.— On carefully examining this specimen I myself obtained, we found mixed with the nettle several broken leaves and a few undeveloped flowers of another plant, evidently the small capitula of one of the Compositæ. The material secured has, however, been insufficient for absolute identification of the plant; but we have made out that in all probability the leaves and capitula belong to a species of Compositæ closely allied to an *Artemisia*. Neither Christison, Taylor, nor Guy and Ferrier in their respective works name either of the *Artemisias* as amongst the vegetable poisons. Woodman and Tidy² class the *Artemisia absinthium* with the poisonous Compositæ, but only to refer to, and quote a case of, poisoning by the oil of wormwood, which oil they call a narcotico-acrid. The other poisonous Compositæ (*Caltha palustris*, marsh marigold, and the ordinary *Lactuca sativa*, and the strong-scented lettuce, *virosa*) which these

authors cite, respectively produce, however, very different symptoms from those observed in the patient. The fact that "everything appeared green to him" would point to the *Artemisia santonica* (the source of santonine) as probably forming part of the infusion of the dried herbs the patient had swallowed. The literature I have been able to refer to appears absolutely silent on the other poisonous qualities of this plant. Pereira,³ in speaking of its physiological effects and uses, cautiously says: "An accurate account of the effects of *santonica* is yet wanting."

Yours truly, ROBERT FOWLER, M.D.

Bishopsgate, May 5th, 1883.

ANTISEPTIC MIDWIFERY.

To the Editor of THE LANCET.

SIR—Now that Listerism as a principle, or system of principles, is so well known and recognized by the medical and surgical world, it is, I think, incumbent upon every practitioner to carry it out in the practice of midwifery.

I have read with great interest the notes of the paper read by Dr. Williams, at the Harveian Society of London, and, as far as my experience goes, I can endorse the opinion he expresses with reference to the incorrect and deficient returns of mortality from puerperal fever. If the reduction in the mortality consequent upon the use of antiseptics in hospitals should not prove a sufficient inducement to every practitioner to try them, that inducement ought to be found in his own prospect of succeeding better in midwifery practice with them than without them, and this prospect is what every disciple of Lister's will at once assure him of. For some time now I have been in the habit of using carbolic oil of the strength of 1 to 15 for anointing the examining hand and fingers. After the examination I simply rinse the hand in warm water without using soap. By the time the child is born I have the oil applied over every portion of the hand and arm likely to come in contact with the maternal parts, so that should it become necessary to remove the placenta by inserting the hand and arm, they have become perfectly aseptic. After labour I give directions to change the bed and body linen on the second day, and the diapers every second hour for the first few days, and order the genitals to be thoroughly washed, morning and evening, with carbolic soap.

I am, Sir, yours truly,

C. R. ILLINGWORTH, M.B.

Clayton-le-Moors, near Accrington, May 8th, 1883.

THE NECESSITY OF TAKING FORCEPS TO EVERY CONFINEMENT.

To the Editor of THE LANCET.

SIR—The above is an axiom laid down by most teachers of midwifery, but, I am afraid, rarely acted on by the general practitioner. My practice has always been to take an obstetric bag containing all the necessary articles to every case of confinement over a mile from home, but when the distance is short to content myself with taking ergot and carbolic acid, unless I know of something in the previous history of the patient that necessitates instrumental interference. The other morning I received a lesson which recalled the aforementioned axiom and brought it home forcibly. Believing the accident to be of rare occurrence, I take this opportunity of placing it on record.

On the morning of October 5th, about 2 A.M., I was called to attend a Mrs. H—, in her seventh

³ Manual of Materia Medica and Therapeutics, 1865, p. 334.

confinement. She had previously a history of normal labours on all occasions, and is a tall well-formed woman, with a roomy pelvis. I found on my arrival that the membranes were ruptured, the head was presenting, and the os uteri about the size of a five-shilling piece, the pains being slight but regular. After waiting about half an hour I made another examination, and found the cervix dilating nicely, the head being still in the normal position. Shortly thereafter she had a severe pain, and cried out for the first time, which made me again examine, to find that the cervix had slipped over the head, which was now well down. Expecting as I did, that the next pain would finish the birth of the head, I kept my finger in position and waited. You may imagine my astonishment when the next uterine contraction sent a loop of cord right into the vagina, pulsating vigorously until the pain developed and the head compressed it against the pelvis, when it did not again pulsate. To take off my coat and proceed to turn was the work of a moment, but, notwithstanding all my efforts, I failed to get my hand past the head, neither could I move the child by the combined method, nor replace the cord. I sent off for my forceps, but had little hope of their being of service, as I knew fifteen minutes must elapse before I could get them. With my finger hooked round the chin and vigorous compression over the abdomen, I caused very considerable expulsive efforts, which made little impression on the advance of the head, so that from the time the cord became prolapsed until the birth of the child fully ten minutes must have passed. I need scarcely say the child did not breathe, and that artificial respiration proved of no avail. Whilst compressing the abdomen during the descent of the child I became aware of the presence of a second, which was literally shot into the world about a quarter of an hour after the first. The second child was alive and strong. The cord in the first case measured forty-two inches in length, and lay loose in the amniotic cavity, being round no part of the child's body; in the case of the second, the cord measured twenty-five inches, and was loose also. Both children presented with the left occiput anterior; each had a separate amniotic sac, and the placenta came away singly. There was no bleeding. Both children were females, and weighed respectively 6½ lb. and 7 lb.

Here was a case of preventable death through failing to have the forceps at hand, a case to me unique, but which, I think, should be placed on record. No doubt there were various factors at work hindering a successful issue. First of all, there was the early rupturing of the membranes, the continuous pressure enfeebling the child; secondly, there was the long cord lying loose; thirdly, the roomy pelvis admitting of the slipping past the head of a loop of cord during uterine relaxation, or rather at the commencement of the contraction; fourthly, the presence of twins preventing turning or any manipulation on my part likely to hasten delivery, as also distributing the force of the uterine contraction, and causing less impression on the advancing head. All these influences would have been innocuous had I had forceps by me.

I am, Sir, yours very truly,
W. H. MURRAY.

Church-street, Galashiels.

HYDROPHOBIA.

To the Editor of THE LANCET.

SIR—An inquest was held before me on the 24th April last, at the Leicester Infirmary, on the body of a man named Toon, aged fifty-six years, a wagoner, residing at Thurmaston, about three

miles from Leicester, who was bitten in the left hand by a dog at Thurmaston on the 20th January last. The man did not obtain professional assistance at the time. His wife dressed the wound, and it healed up in about a fortnight. Symptoms of hydrophobia afterwards disclosed themselves, and ultimately the man was removed to the infirmary on the 21st April, and died there on the following day (according to the medical evidence after a post-mortem) unmistakably from hydrophobia.

It is stated that the dog has not displayed symptoms of hydrophobia; it is alive, and as a fact was at large until Wednesday last, when, in consequence of an application to the magistrate, the owner of it offered to keep it under control until he could sell it.

The house-surgeon at the infirmary stated at the inquest that it was not within his experience that a dog not suffering from hydrophobia could communicate the disease to a human being, and as the case may be of interest to the medical profession, I trouble you with this communication in order that you may bring it to the notice of your numerous readers, if you think it desirable to do so.

I am, Sir, yours faithfully,
GEO. T. HARRISON,
Coroner for the Borough of Leicester.

Leicester, May 4th, 1883.

CASE OF EMPYEMA CURED BY ONE ASPIRATION.

To the Editor of THE LANCET.

SIR—I think the cure of empyema by a single aspiration is sufficiently rare to warrant my reporting the following case. I give the physical signs somewhat fully, as the absence of symptoms in anything like a corresponding degree is curious.

M. E. B—, a girl aged seven, was brought to me by her mother on May 11th, 1882, complaining of want of appetite and gradual loss of flesh, which had been observed for some weeks. No history of a recent acute illness. Her condition on examination was as follows:—Pulse 104; temperature (10 A.M.) 99°6'; respiration 32. The left side of the thorax was almost immovable during respiration, and the lower spaces on that side were flattened, but not bulging; vocal fremitus was absent, and the heart's apex beat was displaced about two inches to the right of the normal position. The percussion note was dull except close to the upper dorsal spines and about two inches below the clavicle in front. In the latter situation it was tympanitic. On auscultation there was silence in nearly the whole of the left chest except below the clavicle in front and near the spine posteriorly. On the right side the expiration was prolonged in apex, and some moist râles were audible at base.

On the following day I entered a small-sized needle in the eighth interspace, about three inches from the spine, and drew off with the aspirator fifteen ounces and a half of laudable pus. The lung expanded very quickly, but ten days later, when I sent the patient to the country, there was still dullness at the lower part of the left lung, but vesicular breathing was audible in the dull area. Her general health was much improved, her appetite fair, and she had gained four pounds in weight during the ten days since the operation. After staying for a month in the country she returned, apparently in perfect health, and has continued so up to the present time. The chest is now resonant throughout, and the breath sounds are normal everywhere. The only medicines used were syrup of iodide of iron and cod-liver oil.

With this case before me I cannot help thinking

that simple aspiration might have had a fair trial in many cases where the more serious operation of establishing a drainage from the pleural cavity has been resorted to at the first.

I am, Sir, yours, etc.,

WALTER WEIR, M.B.

Norwood, May, 1883.

ABSENCE OF LOWER AND DEFICIENCY OF UPPER INCISOR TEETH.

To the Editor of THE LANCET.

SIR—A child two years and four months old was brought to me the other day. Its dentition was different from any I have ever previously seen. The teeth were all perfect with the exception of the lower incisors, which were entirely absent, the gums were sharp, and there was no appearance of rudimentary teeth. There were only two upper incisors, which were very large, and shaped like strong canine teeth of an adult. The family history was good; no scrofulous tendency known.

I would be obliged if any of your readers could say whether they have seen such a case, and whether during the second dentition the want was supplied. I am, Sir, yours faithfully,

JOHN R. HAMILTON, M.D., etc.

Elm House, Hawick, N. B., May 7th, 1883.

PECULIAR COLOR REACTION IN URINE AFTER THE ADMINISTRATION OF GURJUN BALSAM.

To the Editor of THE LANCET.

SIR—I have lately been trying gurjun balsam in chronic gleet discharges, etc., and in examining the urine of such patients I find a very remarkable change of color follows after boiling on adding a small quantity of nitric acid, the urine becoming of a blood-red color, soon changing to a deeper red. This peculiar color reaction is very lasting, as I have found it still existing, though in a less degree, in patients who have not taken any of the balsam for two weeks. The color principle appears to be contained in the balsam, and passes through the system unchanged, for if a watery extract be made and treated with nitric acid, an intense red is obtained on boiling. I should be very glad to have any further light thrown upon it. It seems just possible that a portion of its use as a cure in chronic diseases may be due to its slow elimination from the system. I am, Sir, yours, etc.,

BUXTON SHILLITON.

Frederick-place, Old Jewry, E. C., April 24th, 1883.

IS TENDENCY TO DEATH DURING PARTURITION HEREDITARY?

To the Editor of THE LANCET.

SIR—I was recently consulted by a young married lady aged twenty-two for troubles connected with the early stage of her first pregnancy. She is a fragile little body, of English parentage, but born in India.

Finding on inquiry she was in the habit of staying indoors for days together coddling and reading, I tried to impress upon her the necessity of taking plenty of outdoor exercise, so as to raise her physiological tone to its highest pitch, as a medical man would view with considerable anxiety the accouchement of a woman who indulged in such indolent habits, when she volunteered the following extraordinary statement:—

"My mother, grandmother, and great grand-

mother all died in their first confinement." Her mother married at seventeen and died at nineteen, three days after instrumental delivery, in India. She does not know any of the particulars of the other deaths, only the fact that each gave birth to a daughter and then died.

Out of over 1,500 cases of midwifery I have attended, I am thankful to say I have only had two maternal deaths, and in one of them hereditary tendency seemed to be an influence at work. It is over twenty years ago now. I attended the woman in her third and fourth labours. After the last she died of puerperal mania. The husband, when he called for the certificate of death, said, "It is a remarkable thing; both my wives died in their fourth labour, and they were sisters."

Perhaps some of your readers may be able to give further information on this interesting question. —I am, Sir, yours truly,

W. HENRY DAY, L.R.C.P.

Clayton House, Chapel-street, Pentonville, N., May 21st, 1883.

WHO SHOULD HAVE THE CASE?

To the Editor of THE LANCET.

SIR—Kindly give your opinion on the following case in your next issue. A patient of mine sends for me, saying "his gardener has broken his leg." I am not at home, and the groom goes to my neighbor, who attends to the case. As soon as I return I write a note of thanks to my neighbor, and see the case myself next day. The patient in question has never required any medical attendance since the family came into this part, and consequently I have never attended him, though I have attended his master's family and all his dependents for two years. My neighbor claims to be entitled to the case, inasmuch as the man had never been attended by me before. I claim it, because the master sent for me and intended me to have it, and only called in the other practitioner in consequence of my not being at home. I should add that we live in a village and are on good terms, and in the habit of stopping gaps for one another.

I am, Sir, yours, etc.,

TWENTY-FIVE YEARS' PRACTICE.

May 22nd, 1883.

* * According to commercial principles this case should be retained by the practitioner who first saw it. According to professional ones, it should be handed over to our correspondent. It is the peculiarity and the privilege of medical men to stop a gap for each other, and there is no greater happiness in professional life than to know that in one's absence a professional neighbor will act as one's *locum tenens* without any thought of professional advantage.—ED. L.

DR. JOHN S. BILLINGS has been elected a member of the National Academy of Sciences, Washington, U.S.A.

THE Alumni Association of the Jefferson Medical College of Philadelphia has decided to found a Professorship of Pathological Anatomy in the College in honor of Professor S. D. Gross. This is a very fitting tribute to this distinguished surgeon and teacher, since in his earlier years he wrote a book on Pathological Anatomy which was long used as the text-book on the subject in American schools.

ON

MODERN THEORIES AND TREATMENT OF PHTHISIS.

Delivered at the Royal College of Physicians, London,

By JAMES EDWARD POLLOCK, M.D.,

Consulting Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

LECTURE II.—PART II.

We come now to the experiments of Koch on the bacilli of tubercle, which have attracted so much attention, and seem especially to have awoke the public to the opinion of the specific character and contagious nature of phthisis. I have purposely considered other parasitic diseases before this one, in order that we may see how tubercle is allied to many affections and shares their pathological meaning. We may condense Koch's opinions as follows. By late researches on the tubercle ferment the constant presence of bacilli is proved in recent tubercular formations. These are small, like those of leprosy, but finer, with pointed extremities. Their protoplasm easily colors with methyl blue, the solution having been made alkaline. They are found in great quantity in inflammation of a tuberculous character while progressing; when the height of the affection is past they diminish, as we found in malarious fever. They are always seen in the periphery of tubercular nodules isolated or grouped, in the so-called giant cells, and in chronic tubercle often only in the giant cells. They are always present in caverns mixed with others of analogous form, which do not, however, turn blue with methyl blue; the others take the brown color of vesuvium. In very recent tubercular formations, they are found without the coloring test in bloodvessels, lymphatics, and intercellular spaces. Koch established an artificial culture of these bacilli, making use of the serum of the blood of the ox for that purpose, which he dried by gentle evaporation at a temperature of 122° to 129° F., the coagulation of the serum being avoided. The bacillus of tubercle

must be at a minimum temperature of 94°, the maximum 105°. The bacilli of malaria require a higher temperature. Those of tubercle take about ten days to produce the germs, which cover the surface like scales. With these he experiments on animals (rats and mice). He either introduced bacilli into the blood or into various tissues of the body, and always obtained a positive result—viz., tubercular infection. Nothing occurred in tissues where inoculation was practiced under eight days, the glands inflamed in fourteen days, the general infection of the system took place in six weeks, then tubercle was developed in various organs, chiefly the liver and spleen. In phthisical cases in men half the number had bacilli in the sputa, and Koch never found them in persons not affected by pulmonary tuberculosis. Further, from inoculation with the sputa of phthisis, even when it had been previously dried, he never failed to produce tuberculous infections. The inference would seem to be that a spore producing a bacillus is the cause of phthisis. The opinion and experiments of Crudeli, of Rome, are especially advanced. He thinks scrofulous and tuberculous inflammations distinguished from all other pathological processes which produce cheesy masses by this: that the cheesy masses contain the tubercular contagion, which is proved by the inoculation of rabbits which reproduces the tuberculous inflammation. The cornea of the rabbit inoculated with tubercle evidenced inflammatory action after twenty days, from which tubercle can be reproduced. Tubercle in its earliest days has in its centre a mass of very minute granules, with a small bloodvessel or lymphatic. These granules are not the fatty albuminoid detritus of tissues, for they resist the action of alkalis and ethers. The granules in tubercle are micrococci; they multiply themselves in the blood, and in tissues where scrofulous inflammations are present. A wounded part will be invaded by them if inoculation occur. Bacilli are found in the tubercular nodules, and the peculiar contagion is probably in these. It is found endogenous—that is, it is produced and multiplied in a system affected by what he calls tubercular sickness. It is transmissible from the sick to healthy persons; is found especially in localities where tuberculous men, or animals as oxen, are grouped in numbers; in the morbid secretions of affected organs; in the liquids of normal secretions, and notably in milk. It can be transmitted by using the milk of tuberculous cows, they being very liable to that class of disease.

Klebs made animals tuberculous by feeding them on the milk of tuberculous cows. Lockmann, of Christiania, found a whole population in a district of Sweden, previously free from tuberculous affections, become so soon after the introduction of a breed of Ayrshire cows which were known to be affected by that disease. On this evidence Crudeli asks whether man did not originally derive tubercle from cows through their milk. He says it is a matter of historical record that America had no tubercle before its discovery by Columbus, and the introduction of European population who imported cows. There were no mammiferous herb-eating animals on the American continent previously, excepting the llama of Peru. On this point I think we shall agree to await further evidence. Crudeli considers that tubercle can enter the organism in intra-uterine life through the placenta, also by the father communicating it to the ovum. Tubercular metritis in the female and prostatic tubercular disease in man can infect. The contagion may also enter by the respiratory tract; to breathe the air where many consumptives are assembled, as in hospitals, may turn out very dangerous, and he thinks this is proved by the experience of the Consumption Hospital. The disease is especially communicable from husband to wife. Wounds exposed to tubercular air can be also infected.

Tubercular infection is either primitive and local or general, but in all cases infectious. In those which seem obscure there is some part of the vascular system already the seat of infection, but the general infection is always due to a local primary one. The matter is conveyed by bloodvessels and lymphatics; it forms new foci in glands and organs, where the infection multiplies itself till the whole system is engaged. These foci or stations are determined by local congestions and injuries, producing a diminished resistance of the tissues. Some persons escape the contagion to which they are exposed, as the physiological activity of the tissue, and especially of the circulating powers, hinders the contagion from taking effect. Even when the entry of tubercular infection has occurred, it is limited to that spot of entrance for a time, it being necessary that the condition of the organism be such as to permit the contagion to fix itself and to multiply in it. If it does enter the system it is eliminated by the secretions, the skin and kidneys especially. Crudeli, Koch, and others acknowledge the tubercular habit or constitution, of which they consider that some elements are known, and they confess to a predisposition to tuberculosis. Such are diminished respiratory capacity, lessened cardiac and arterial power and tension compared to the bulk of the tissues. Puberty and rapid growth, the lymphatic and scrofulous habit, incline to phthisis. This is probably caused by the incomplete drainage of any part by the lymphatics, by which a great vulnerability of the lymphatic system is induced. It is confessed that these abnormal conditions can be acquired by bad physical education, deprivation of fresh air, and exercise, etc.; but, again, it is acknowledged that it can be both hereditary and congenital. The difficulties of the therapeutics of such an affection are dwelt on, and I shall again have occasion to notice them; but will mention here that, according to this theory, in every node of tubercle the central part contains the contagion, while surrounding this there is a zone of dead tissue in which circulation has ceased. Across this zone the specific ferment can pass in the interstices between the cells; but the therapeutic agent cannot pass, and has already been greatly diluted in the mass of the blood. The same observation has been applied to the thickening of tissues surrounding syphilis. But, granting

that we have arrived at the fact that in all tubercle, or so-called tubercle, and in all the secondary structure changes of phthisis we can recognize a certain parasite, in what manner do those changes manifest themselves in the system?

Perhaps a division (made by others) may be followed with advantage—namely, septic acute changes and specific changes. In the former we must class infection from wounds, putrid matters, the exanthemata, erysipelas, diphtheria, typhoid, malaria; in the latter syphilis and tubercle, and perhaps rheumatism. Septicæmia is distinguished from all others by its short incubation period, and by its not having any elective seat in the system: for it pervades all tissues with rapidity. Typhoid, variola, and the exanthema, with diphtheria, seem to have selected tissues in which to germinate, as the intestine in typhoid and the nerve-centres in diphtheria. Rabies stands alone with a long incubation period and an acute final crisis, but in this it is resembled by rheumatism.

Taking, however, all diseases attributed to parasitic germs, excepting septicæmia, there seems to be a mode of evolution in common. They all have to find a nidus or station—a tissue of the body, in fact, selected by, and peculiar to, that particular germ in which it can, and does, mature and fructify. The incubation period, be it long or short, is just this time in which the seed is undergoing those changes which a grain of wheat does in the soil of the earth. That particular grain dies, but in dying multiplies itself indefinitely. The new germs are let loose into the circulation and lymphatics, for they are small enough to enter the smallest of these vessels, and then a fresh colony is formed in another site, perhaps in another organ. At the date of the first settlement of germs in phthisis there are febrile symptoms and inflammatory products, or so-called tubercle, in a localized part. During the incubation period there is a pause, be it diurnal or of days, or even a longer interval; and at the first evolution of new germs there is renewed pyrexia, and either extension locally of the first mischief detected in an organ, or a secondary nidus of disease set up at a distance. Taking the malarious disease in its common form of ague, the cold stage is that of first evolution of germs into the blood; they diminish in the hot, and die in the remission period. The pause is the incubation period, followed by similar phenomena in a cycle.

Now, applying this theory to phthisis as we see it, we have much that is plausible in this matter-of-fact way of interpreting its symptoms. The seed-sowing time, the period initiative of active symptoms, when the patient is in a subfebrile state, with few or no signs of local irritation in the lungs, is the time when he has received germs into the economy, and which he has failed to eliminate. The evolution period is that highly feverish state, with slight remissions, when the inflammatory or tubercular product is breaking up. At such time, say the theorists, the new crop of germs is being let loose into the system. At this period all the secretions are apt to be disordered, that of the skin and kidneys especially, and diarrhoea often sets in. An elimination is being attempted, and, perhaps, fails. Just then we often find a doubtful sound of crackle, with a little dulness of the apex or base of the opposite lung, and here is now a nidus station, or colony of the germs, which have been formed at the first station and been carried hither by the known channels of the circulation or lymphatics. The pauses or subsidence of symptoms in phthisis are very familiar to us, and we are asked to believe that they are the periods when the seed sown is again silently preparing a new crop in the soil of the tissues. The third period of local dis-

case, when much structure has broken down and a pus-secreting surface is formed, is known to abound in these bacilli, which are abundantly found in the sputa and other secretions of the patients.

I come now, Sir, to the crucial question whether, granting that these parasites are found in all cases of phthisis, granting that their inoculation in animals will produce a like disease, are the clinical phenomena of phthisis sufficiently accounted for by the germ theory? and in the few observations which I shall make I must ask you to class me as an inquirer and not as an advocate, being well assured that you are yourselves precisely in that mental attitude of impartiality which is open to the reception of new truths, but repellent of obvious error. The story of phthisis is commonly this. In certain persons, whose constitution is predisposed, or who have inherited a predisposition to a form of disease, and most commonly at a certain age, with or without actual cold taking or manifest cause, a slight wasting occurs with a subfebrile state followed by pulmonary symptoms, as cough and expectoration, and blood-spitting. A physical examination reveals incipient disease in a portion of lung. As regards heredity, this sequence of events is so common in some families that a whole generation will be carried off at about the same age. The sickness I am describing will take place without any exposure or direct contact with persons similarly diseased. Nay, it will occur to the members of the same family living at the greatest distances from each other, some in America, some in England. There is another form of disease called accidental, because it is not proved to be inherited from an ancestor, and seems to be due to causes of local origin, as taking of cold, pneumonia, etc., and this again without previous contact with persons similarly diseased.

Are we to believe that both varieties, the inherited and accidental, are instances of seeds, that is germs, introduced into the system from without, and there producing the characteristics, multiplication and fructification, which we have been studying? Or, if germs, then in the inherited form were they derived from the parent? This implies a long latent period of years during which the germ has been there but produced no effects on the system? Again, the introduction of such germs into the system in other than inherited cases should be a matter of proof and certainty before the theory can be received. A person falls into ill-health from depressing causes, as poor food, bad dwelling, anxiety, loss of sleep, and such like, and becomes phthisical, but where are the germs? The theorist will tell us that in such a state the individual we have supposed presents the exact soil suited for the reception and growth of such germs of disease. And so it is; but the field well ploughed and manured and ready for the seed-sowing will produce no grain unless the germs are introduced. The theorist will no doubt say, as regards the hereditary cases, that the seed was sown before birth; but if this be true, what a long period of incubation it has required. The introduction of the germs seems to me to be a difficulty yet unsolved. It is not sufficient to prove that germs introduced will bring forth fruit. This indeed seems clear from the evidence, but that such germs have been sown as an antecedent to all cases of phthisis has not been proved, and must be proved before we can accept the proposition in its entirety that phthisis has its origin in parasites.

In pursuing the clinical history of phthisis, we must, however, acknowledge that in its later stages the theory of the fructification and multiplication of germs harmonizes well with what we

observe at the bedside. The theory is that the germ has first a local position—say in the lung—that after a period of incubation it multiplies, and that parasites are carried by the blood and lymphatics to another and distant part where a colony, or station, or nidus is formed, a fresh deposit of morbid parasitic matter taking place with the same phenomena as in the first local irritation and general febrile disorder. Now, the story of phthisis is well known to consist of exacerbations and remissions, and the history of secondary deposits of miliary tubercle, of secondary infections of the opposite lung, and of the small intestine and of meningitis, singularly corresponds with the theory we have described. In the latest stages of cavity-bronchiectasis, etc., the phenomena are often more septic than specific; yet, if we may adopt the germ theory, we have a ready solution of the clinical conditions. The presence of a peculiar germ appears to be proved, and its secondary results seem demonstrated; but its originating power, its being the sole and invariable cause of the disease, seems scarcely proved. Comparing the tubercular germs with those of other parasitic diseases, we may have some light thrown on the *modus operandi*. Take malarious fever. In the experiments I have detailed it seems certain that malarious micrococci can be detected and cultivated and inoculated, with the invariable sequence of certain symptoms, the blood examined containing more bacilli in the invasion stage and less in the hot and sweating stages of ague, while in the remission period they nearly disappear. The poison is peculiar to certain localities, persons not visiting those places do not get the disease. It is proved to be non-contagious—that is, no contact of individuals will convey it from one to the other. The nature of the attacks and remissions so resemble phthisis that I have selected it first for comparison. If phthisis be contagious, why is not malarious fever or ague also?

I take, again, rheumatic fever, in which the bacilli are most marked in the fibrous structures and muscles, the endocardium, etc. Its symptoms also are acute pyrexia with profuse sweatings. It is one of the most heritable of diseases, and runs in families to a remarkable extent. What of the germs? Were they congenitally introduced; or were they acquired from outside? What of the latent or incubation period? A man will often have an interval of seven or ten years between the attacks. Are the germs there, but latent for all that time? Is it that they have not reached that part of the system capable of assisting in their multiplication? This can scarcely be, seeing that in some former attack a nidus may have already been formed in a joint or in the mitral valve. Again, has ever anyone supposed rheumatism to be contagious? In syphilis we certainly find a more close analogy to phthisis than in the other affections named. Granting the introduction into the system of a definite poison by an ascertained inoculation, we find a long latent period followed by characteristic symptoms—skin rashes with pyrexia, and deposits in distant organs: the brain, the tongue, the periosteum. The theory of successive developments of parasites will fit in here; or rather let us say that, parasitic or not, an infecting material first found in the hard chancre has passed through the blood and lymphatics and manifested itself after a long interval in distant parts. Its identity with the inoculated spot is further evidenced by its amenability to certain specific remedies, as mercury and iodine. We see in both syphilis and tubercle a selection of certain tissues, and we may contrast this with purely septic infections which seem to develop germs in all tissues and membranes.

But beyond all these analogies, and lying deeper in our pathology than any discovery of parasites, are other questions. Can all the systemic phenomena of such diseases be accounted for by accepting the proposed theory? Let us take phthisis tubercle, excluding miliary tuberculosis in its acute primary form. If asked what are the prominent systemic characters of phthisis, we should reply fever and waste. The characteristics of fever are disintegration of the living substance of the body, and increased and diminished constancy of bodily temperature. Fever is not merely a state but a process, and, as Burdon-Sanderson says, has had its beginning in the entrance into or action on the system of some affecting or infecting cause. The cause of waste is a consumption of albumen, which passes out of the system as urea, and which is derived either from blood-corpuscles, or from muscular detritus, or from both. It is probable that a breaking down of the blood-corpuscles is a part of the febrile process. The coloring-matter of the blood is the means by which oxygen is distributed to the tissues, and the destruction of it must impair every function of organic life. In fever the excessive nitrogen and carbonic acid passing out of the system is supplied by the waste of muscle and of blood-corpuscles. The same authority remarks that the tissue origin of fever is the basis on which we hope eventually to construct an explanation of the process. Fever probably originates with living tissues, and is from first to last a disease of the protoplasm, to which all systemic disturbances are secondary. He adds that at bottom we are all humoralists and believe in infection, and that fever is tacitly assumed to be the product of a material fever-producing cause contained in the blood or tissue juice, the morbid action of which on the organism is antecedent to all functional disturbances whatever. In applying these facts and theories to phthisis we may see how large a question is the pathology of that disease, and how inseparable are its phenomena from those produced by other affections accompanied by elevated temperatures and waste. That it has some analogies to purely zymotic disease is undoubted, but the question may fairly be asked whether in the absence of proof of the entrance or inoculation of any germ it is not possible to conceive blood changes which may originate the train of symptoms. The moment that the blood is overlaid by nitrogenous material, its corpuscles destroyed, and the detritus of muscular waste poured into it, we are assured that the presence of bacilli is manifested. In all degradations of vital fluids, nay, of all organized structures, do we not observe the same law, the development of parasites? Those more evident to our senses, as all the parasitic worms, assail the enfeebled body and enfeebled tissues, so many parasites, and in the vegetable world innumerable lower growths, become manifest when the organization of the tree or plant is impaired. May it not be so also in those blood changes which precede the development of tubercle? May it be possible that the bacillus is the consequence, and not the cause, of the disease? the lower organization which replaces the healthy blood-corpuscle? In the present state of our pathology it is impossible to answer these questions, but thoughtful inquiry will consider them in weighing the evidence which time and experiment will shortly develop on all sides. For we cannot stop where we are, nor at once accept as a solution to all our difficulties the theory which has its avowed basis in experiment and not in clinical observation, and which is as yet rather the fruit of the laboratory than of the hospital.

LECTURE III.

MR. PRESIDENT AND GENTLEMEN—In considering the whole modern history of researches into phthisis, its nature and its difficulties, we are struck at once with the return to Laennec's original doctrine of the specific character of tubercle. That there is a definite product, an entity with peculiar and distinguishable characters, with invariable results, and that the disease of phthisis is a pathological unity, have become more and more the doctrine of the day. Be tubercle what it may, it is now more defined than ever; and if we can assign to it an unvarying cause of production, an origin constant and unique, in a germ-producing bacillus, we have certainly receded from some late teaching. If tubercle, or those small masses seen on the lung and prone to cheesy degeneration, be only common products of ordinary inflammation, as some have taught, we must believe that ordinary pulmonic inflammation, if it affect the walls of the alveoli and the interlobular tissue, has its origin in the parasitic germ. Koch attributes miliary tubercle and all cheesy degenerative nodules to the bacilli. He has inoculated with them all, and found the same result.

Since Koch's observations have been published there have of course been many experimenters anxious to prove or to disprove them, and we have already numerous records of their experience. In Germany, Fränkel found bacilli in 120 cases of phthisis, which were all he examined, and Heron in sixty-two cases. Dr. Dreschfeld, of Manchester, has contributed most valuable observations. He found the tubercle bacilli in all cases (forty-six) of phthisis where the physical signs were well marked. He has also examined six cases of bronchitis and emphysema, one of bronchiectasis, and two of fibroid phthisis, without finding bacilli. Of catarrhal pneumonia he had three cases with the same result. In two well-marked cases of lung disease there were no bacilli. Taking cases of tubercular disease of organs other than the lung, Fränkel found bacilli in fifteen out of sixteen cases in the secretion covering laryngeal ulcers, and Crudeli found them always in the stools of tubercular enteritis. Rosenstein also found bacilli in the urine of a patient who had tuberculous disease of the epididymis, the lungs being free from disease. Fränkel also in the pus of a scrofulous joint. We thus seem to have it proved that bacilli are present in all tuberculous disease, and absent in non-phthisical lung affections.

As regards the stage of lung disease in which they are most prevalent, observations show that it is rather in the later stages that they are in greatest quantity. Our evidence hitherto also seems to prove that their greater number is accompanied by a higher degree of pyrexia, and signifies a more acute form of disease. On this point further observations are necessary, and the same may be said of acute miliary tuberculosis, about which we have hitherto no evidence. My colleague, Dr. Williams, has examined the sputa in 130 cases of Brompton Hospital. Of these, 109 were cases of phthisis, cavities in eighty-one; nine were cases of early consolidation. Bacilli were found in all of them, excepting three. There were twenty cases examined of other lung affections—bronchitis, bronchiectasis, pleurisy, empyema, pulmonary congestion from heart disease, but bacilli were found in any of them. Of the cases of phthisis, there was pyrexia in fifty the temperature ranging from 100° to 105°. The fact of Koch's discovery as sufficiently established, and that, bacilli being found in all cases of phthisis, they stand in the position of a causative agent, and taking also into due estimation the

persons exposed do not get the disease, we have to inquire whether there are not antecedent conditions—that is, conditions prior to the introduction of the germs—which favor their development. There is, we may assert, a state of health, or of constitution, or of lung, which is a main factor in the induction of disease. It is here that the old pathology meets the new, and we imagine that it will be found that in all instances there is a pre-existing state which prepares the way for such germs as shall be accidentally introduced. This consideration demands our earnest attention. The period to which we allude is as much a first stage period as is the manured and prepared bed in the garden to the crop which is to grow in it. It is probable, nay certain, that germs daily enter the air-passages and take no root. The two factors of heredity and inflammation are those which all recognize as difficulties in the way of accepting off-hand the bacillus theory. But they seem to be the agents which exactly prepare the way for the reception of infective germs. In the first lecture we dwelt on the evidence for the presence of inflammatory products in all cases of phthisis, and it is so proved that it cannot be omitted in any theory of the disease.

Let us examine what heredity and inflammation do and how they are supposed to act. Heredity may mean not only a germ conveyed by the parent or more remote ancestor, but may, and in fact often is, a weakness of constitution, a tendency to disease, an especial vulnerability of lungs, and proneness to their inflammation. As Dr. Green has remarked, the tendency to retention and accumulation of inflammatory products is a leading character of scrofulous inflammations. An inherited proclivity to phthisis favors congestion. It is also conceivable that a want of tone of the bloodvessels is inherited, with a general deficiency in the power of products of the circulation, which no doubt favors transudation of low vitality. On the whole, then, a want of resistance to such attacks is held to be the most likely preparation of a bed which will grow bacilli. A mere exposure of the bronchial membrane is not considered sufficient for their development, but their entrance to and impaction in the alveoli.

Another question which has been dwelt on by Dr. Green and others is the condition of the apex of the lung. The common localization of tubercle in the apex has been referred to a diminished range of movement tending to stagnation in the pulmonary capillaries, a state which is closely allied to congestion and the formation of inflammatory products. In this manner a nidus or bed is formed fit for the reception of germs, and ready to reproduce them. Thus the old pathology joins on to the new, and we carry the idea of inflammation as a necessary preparation for the reception of the bacilli. It is indeed essential to conceive some such preparation for the elaboration of the germ into an established disease of specific character, and it also accounts for the innumerable cases of exposure to contagion where no disease results, for we must uphold that clinical experience is against the contagious nature of phthisis, and that something more is required than the mere presence of the organisms. Again, we would say that the recognized observation that the walls of the alveoli are essentially engaged in true tubercular disease favors the bacillus theory, the germs being found in that position. We seem, then, to have advanced from one pathological view to another, and, if Koch's observations turn out to be correct, he has discovered that specific element of disease to which all advancing pathology pointed, and which the best observers were expecting. It is not a contradiction of their observations, but an

addition, which is not out of harmony with their results, and may even account for phenomena for which all previous reasoning had failed to find an adequate cause. It is in these subtle causes which influence the constitution as heredity and sexual transmission of tendencies to disease, and even of particular forms of disease bearing the same name, that we shall find ground for referring the germ theory to some deeper line of argument than can be resolved by a chemical experiment. Whole families are liable in a peculiar degree to phthisis, to rheumatism, to typhoid, to diphtheria, or to scarlet fever poisons. They seem to have been born with a proclivity which others have not. Is phthisis always the result of contact with diseased persons? Is the seed always sown at a given time, and can we gather more than one kind of fruit from a definite germ? Again, is it not possible to account for the phenomena of phthisis in another way? Granted that a given cause has originated a local deposit in the lung, do we see more in the symptoms of irritative fever so initiated than can be accounted for by the local cause of impacted alveoli, with compressed and strangled walls, pressure on the nutritive and pulmonary vessels, and resulting necrosis? Only last year we should have said "No." Again, are we to class all diseases from germs as of one or two kinds, say, septic and non-septic? There is a vast difference between the infection from the spirilli of anthrax and the bacilli of tubercle, as we have seen both in the incubative and crisis periods, in the latency and intensity of the symptoms, yet some of the later symptoms of phthisis are very like septic poisoning.

The question of the contagious nature of phthisis is one which cannot be decided by experiments of inoculation alone. They go a long way towards establishing a likelihood, but must be backed by clinical evidence of the largest kind. In discussing the question we are met in the outset by the fact that other diseases in which infective germs are found are well known not to be contagious—that is, capable of being communicated by one individual to another. The malarial poison and rheumatism are illustrations, as is also pneumonia of the acute or croupous variety. In the latter, according to Crudele and Koch, micrococci are found in the exudation in the alveoli of the lung, in the pia mater in cases of pneumonia with meningitis, in red hepatization, and in the interalveolar tissue. The clinical evidence will have to prove that in a large number of cases, not to be accounted for in any other way, phthisis has been conveyed from one person to another; it would also be expected that the poison would be intensified by the grouping of large numbers of diseased persons together, as in the Consumption Hospital. As a very remarkable outbreak of disease occurred in my own clinical practice at Brompton Hospital, I may with advantage quote it here. A few years since, in the old building at Brompton, an error was discovered in the ventilation. The system of Dr. Arnott had been adopted when the hospital was built, by which air was driven by a fan at the basement through various air-passages which permeated the building, in the walls and under the floors. There was no extracting power used, but the wards were furnished with the usual Arnott's ventilators opening into the chimneys. A serious outbreak of erysipelas occurred in several of my wards, which were in the terminal part of the system of air-passages—that is, in the portion furthest removed from the entrance of air at the basement. We had many cases and several deaths. This event led to an examination of the system, when it was found that really no air at all found its way into those wards by the shafts, the propelling power at the basement being quite insufficient. There had been

several preceding but more slight outbreaks of erysipelas, and more than the usual amount of "hospital throats." The ventilation was immediately rectified, and the system of extraction substituted which now works so well both in the new hospital and the old one; and since then there has been no more erysipelas. Now we may ask why had we not an outbreak of phthisis among the sisters and attendants instead of an attack of erysipelas? The germ was evidently septic, and produced its customary effects; but the bacilli of phthisis must also have been present in great abundance in the unrenewed air, and ought to have produced the characteristic results. I may mention here that bacilli in fair numbers have been discovered in the air of the extracting shafts of the hospital, which carry off the used air from the wards and passages.

Regarding the experience of the hospital since it was established, the evidence has been most carefully collected by several observers—by my late colleagues, Dr. Cotton, Mr. Edwards, the late resident medical officer, and more lately and completely by my colleague, Dr. Williams; and as this comprehends by far the largest experience of phthisis to be found in any country, I shall here condense it for our use. It is the more valuable as Crudeli has expressly quoted the evidence of the Brompton Hospital to prove the opposite. I think it can be shown that after an experience of thirty-six years during which the hospital has been established, not only has no infecting process been evidenced, but that the medical officers and nursing staff, and the officials and servants have been unusually free from phthisis. Three different forms of infection are possible: first, that by inhalation of the air breathed by phthisical patients, or of the germs set free by their secretions; secondly, infection by marriage, which partly includes the first, the husband and wife commonly occupying the same room and bed, but impregnation by one diseased parent may, through the ovum or placenta, affect the offspring; a third is stated to be by milk of diseased animals, or of the mother. The first will engage our brief attention now—namely, that from contact with phthisical persons, and breathing the same air. The hospital began with 90 beds, increased in 1856 to 200. At present there are 240 beds in use. The ventilation, which I have described, was very faulty in the earlier years, but has now for a long time been carried on by extraction of the used air, which has been proved to produce complete change of the whole air of any ward at least twice in one hour. The faulty system of Arnott was, however, adopted in one wing, that first built. Three-fourths of the cases are phthisis in all its stages. The others are pleurisy, empyema, bronchitis, asthma, and heart disease. In the old building the dispensary rooms were bad, and in direct communication with the out-patient department, where from two to three hundred patients attended daily, most of whom were consumptives. The residents in the hospital comprise medical officer, lady superintendent, four clinical assistants (who reside for six months), sisters, nurses, and servants. All the resident medical officers are now alive, and all the matrons but one, who died in advanced age. About one hundred and fifty clinical assistants have held office. They work in the wards and spend much of their time in the post-mortem room. Eight of them are known to have had consumption, generally at long periods after leaving the hospital, but none had it while resident; one had hæmoptysis before coming into residence, and in only one instance was it clearly proved that the disease was contracted while in the hospital. The sisters sleep in rooms communicating with the wards and gal-

leries, and have a system of ventilation common to the patients. The nurses sleep in rooms above the wards, but of course are all day in attendance on the sick. In the course of thirty-six years only one had consumption while in the hospital. She married a consumptive patient, and ultimately died in the hospital. Three died of phthisis some time after leaving the hospital, two of whom were attacked many years after. Since 1867 there have been one hundred and one nurses, of whom one died of phthisis some time after leaving. The gallery-maids scrub the wards daily. We have had thirty-two since 1867, but no case of phthisis occurred. Of porters most of whom have to work in the dead-room, we have had twenty, none of whom had phthisis. Of dispensers, we have had twenty-two. Among them three cases of phthisis, one of whom only was ill while in the hospital; the other two contracted the disease after leaving, one from intemperate habits. There have been twenty-nine physicians and assistant-physicians, of whom eight have died; one only died of consumption, which he had contracted before his appointment. There have been four chaplains, and nine persons in the secretary's office, but no phthisis among them.

Regarding the communicability of phthisis from husband to wife and *vice versa*, Dr. Hermann Weber's cases, published in 1874, give support to the opinion that the disease is communicable in this relation, and eminently from the husband to the wife. In the cases of thirty-nine diseased husbands, the wives of nine of them became consumptive after marriage, or taking second and third marriages into consideration that in fifty-one cases eighteen wives suffered from the disease. In comparing this with fifty-one marriages between healthy husbands and wives, we certainly do not find such a proportion of consumption among the wives. He found also that in twenty-nine marriages between consumptive wives and healthy husbands, only one husband became consumptive. He thinks that this disproportion can scarcely be explained by the ordinary means of intercourse. The wife, it is true, runs greater risk than the husband through nursing her husband much more closely, and so being more in the atmosphere of the sick room, but this does not explain the great preponderance of wives in the present case, for with scarcely an exception the husbands were in good health, not one being confined to the sick room. Dr. Weber considers that a more likely cause is to be found in impregnation and infection through the fœtus. And so far as his data go he found that wives who do not become pregnant are more likely to escape infection. He remarks on the great rapidity of the form of disease in the wives and its slowness or quiescent character in the husbands. The remarriage of consumptive widowers thus becomes a serious problem if these facts prove to be of general application. My colleague, Dr. Reginald Thompson, considers that he had seen fifteen instances of wives becoming infected through nursing consumptive husbands out of a total of 15,000 consumptives. He evidently inclines to the opinion that the symptoms of phthisis in these cases are rather due to septic than specific tubercular germs, the latter phenomena being pyæmic in most instances. In these communicated cases the symptoms were acute, and the morbid appearances almost pyæmic. My own experience, which has not been inconsiderable, and has extended over thirty years of hospital and private practice, does not supply other than occasional instances of the apparent communicability of phthisis, either in the case of husband and wife or of attendant on the sick. In families whose members successively fell victims to the disease, the attack seemed rather due to the peculiar age at

which persons closely related by blood begin to exhibit its symptoms. On the other hand, I have seen many instances in which the most assiduous personal nursing of the sick, living in the same room, sleeping in the same bed, and undergoing the same influences of air and lodging, of anxiety and harass as the sick, has failed to produce it. There have been waste of flesh and strength, loss of sleep and appetite, and all the evidence of depressed vital powers in numerous cases, but no phthisis. The apprehension of the disease has added to the risk, but the tried and trusty attendant has outlived the trial, and survived (often unwillingly survived) the object on which these attentions have been unselfishly lavished. This, too, has occurred again and again where an inherited taint has rendered the disease most probable to invade. But I confess that further and searching investigations are needed on this question, investigations which shall extend over this and other countries, which shall not have been dictated by already formed theories, and which shall stand the closest and most impartial scrutiny. As I shall presently notice, the result is of the gravest social importance, and is one on which the profession will often be called upon to decide in varied domestic problems, influencing the lives and happiness of families. In Southern Europe the opinion of the contagiousness of phthisis has long been held, and in Italy especially, where I have often witnessed the expense to which surviving relatives have been put after a death from phthisis in a lodging or hotel. I fear that the advanced views of Professor Crudell in Rome will not tend to lessen this apprehension of contagion nor render the residence of consumptive invalids more agreeable in that city.

In approaching the subject of the rational treatment of phthisis, that is, its management, according to our latest knowledge of its causes and progress, we are met on all sides by problems and difficulties. Our first and most natural division of such a subject is into prevention and cure. But what have we got to treat? a specific disease blocking the lung with nodules? an inflammation? or a parasite? Further consideration would lead us to the question of stages. If we have settled what is the cause, the true *materies morbi*, we shall have to regard it in its receptive or initiative stage, what used to be called the hopeful stage of phthisis, when cure was said to be possible; and secondarily, in its structural change stage, when structural mischief is established and parts of the lung are broken down. In the attempted division lie the difficulties of phthisis, yet in the present day especially they must not be put aside with impatience, nor handed over to empiricism, which is one of our dangers. With new theories there are always waiting men who say this is the cause of the disease, behold the cure! Yet this complex affection only still more shows its complexity when we come to apply theory of any kind to practice. We are, on approaching it closely and with impartial minds, struck with the fact that its phenomena are of mixed pathological import, and quite other than unique and constant. Let us take the first question. Is it a specific tubercle, or an inflammation, or a parasite? Judged by its pathological and clinical history, it is each and all of these at once. We find a disorder of local irritation and a pyrexial constitutional state; we find a period of quiet invasion, followed by one of much disturbance and proceeding to recognizable structural destruction—this is the story of inflammation of lung structure, and of the breaking up of the product involving death of surrounding tissues. Yes, but it is the story also of a germ introduced from without, lodging in the lung as a

nidus, fructifying and multiplying, and discharging bacilli into the blood and lymphatics. After a while we find perhaps a secondary centre of disease in the opposite lung. It is a second nidus or station of germs, says the parasitic theorist; it is the detritus of caseated material or a fresh military eruption, says the tubercle believer; it is a fresh inflammation-product centre, says a third. Anyhow, our patient is fevered and wasted, and physical evidence shows that he has one diseased spot, if not two, in the lungs. The treatment of such a state of things (I mean pyrexia, waste, and physical signs of a solid patch in a lung) used to be by local depletion and salines, and we have also seen the dulness over the lung diminish, and the patient relieved from cough and pain and pyrexia, by such means. Whether we were treating a tubercular deposit or an inflammation or a nidus of parasites, we were doing good to our patient. My own belief is that whatever was the primary cause of the lung irritation, we were procuring the absorption of purely inflammatory products in the lung. Practical men will probably agree with me. A study of its phenomena, then, will scarcely assist us in defining its cause, and if it be any of those insisted on by different schools, the practice does not, hitherto has not, varied with advantage to the patient. The believer in parasites will, however, tell his patient to inhale antiseptics, on the theory that their destruction will be accomplished in the lung and their multiplication prevented. However, even the theorist will acknowledge that there are other products in the lung besides bacilli, others even more removable. The introduction of remedies of sufficient power to kill parasitic germs through the blood and the diseased tissues has been, of course, advocated. But it has been well proved that this same cause which has cut off a portion of lung by strangling its vessels, has also rendered it very impervious to remedies approaching it through the circulation.

We fall back, then, on consideration of prevention. If it were possible on the parasite theory to prevent the introduction of germs into the system we should have no phthisis. Sow no seed, and you will have no crops. I suppose that those of us who, like myself, have tried to amuse their leisure with a garden have found less trouble in getting seeds to grow than in exterminating weeds. You dig up, burn, destroy, and after a few years of this preventive work you will have a tolerably clear area, and with excessive care may get on with only ordinary weeding. But still you will find that your soil is peculiarly suited to the production of certain rapidly growing, wide-spreading weeds, which, like the tares in the wheat, choke the healthy plant. The seed-germs, you know, are in the air, sailing on feathered wings, or hidden in the soil till spring comes, growth time; or they are of insect production, and a bird of the air has borne them; or an unseen wind has dropped them on the appropriate spot where their reproduction is certain. Such as this is what farmers call "blight." You sleep, and rise, and your potatoes or hops are covered with germs. There seems to me to be a very close analogy in all this to the germ theory of phthisis. The weed or blight and the germ theory of disease are like living organisms seeking a nidus for multiplication. On the other hand, receptivity of soil is an essential requisite to reproduction. To destroy germs, or to prevent their access and to render the soil unfertile as regards the weed, are the two problems. In an extensive experiment on sweet peas I found that the snails ate up all the seed in the earth. I applied nitrate of soda, when the snails vanished, and a second sowing on the same spot immediately produced the flowering plants.

I had destroyed the animal life, but rendered the soil fertile for the vegetable seed.

We have already noticed that all the theorists acknowledge a certain vulnerability of constitution which predisposes to the reception of the germs of disease and to their fructification. This seems essential to the production of tubercle, of specific inflammation, of parasitic bacilli. It is heritable and peculiar to certain ages. A concentrated heredity will invite phthisis at an earlier age than it would otherwise be due, and in a more intense form, as where both parents were consumptive. This constitution or proclivity is a well-recognized and perfectly proved condition; and it stands apart from all theories of the nature and proximate cause of the tubercular disease, and must be considered in every argument on the subject. It forms the receptive soil, without which, in the vast majority of cases, the germs will not take root; for all of us are exposed to germ agents, but few of us get the disease. If, then, we are to begin with prevention, we must counteract the constitution and prevent the vulnerability. The marriage of persons predisposed to phthisis or already phthisical should be forbidden. Where consumption is already in a family, the marriage of cousins would precipitate the malady, and ought not to take place. All that is invigorating in residence, habits of living, and diet should be strictly enjoined, and the open-air life insisted on as far as is possible. A hardening process of the surface of the body should be practiced by cold sponging and exercise in the fresh air; and sleeping chambers should be spacious and not overheated. But I need not here dwell on the recognized mode of dealing with those who are delicate but not diseased. If we adopt the parasitic theory—that is, that germs can be introduced from without by contact with a sick person—such contact should be forbidden, especially the occupancy of the same room or sleeping in the same bed with consumptive persons. I see no less stern an injunction than this to be possible to those who consistently believe in the germ theory. While we cultivate all that encourages the vitality and resistance power which we know to be hostile to the advance of disease, we are bound to protect those most exposed to its ravages. But if we seem to have it proved that we are exposed to a danger little suspected before from contact with the sick, there is a possible compensation to be found in the doctrine of the culture of germs by artificial means. In the experiments with the spirilli of anthrax it was found that by passing them through many animals, thus securing a repeated generation of the parasite, the intensity of the poison was greatly increased, so that an infinitesimal quantity sufficed for inoculation. But, again, it was found that by culture and reducing means applied to certain ferments, as those of splenic fever in the lower animals, the intensity of the poison could be reduced, as in the experiments of Büchner, who was able to mitigate the poison of the anthrax to the comparatively harmless "hay bacillus." There is a hope, therefore, in the minds of some that it may be proved possible to reduce the power of tubercle parasites by passing them through lower animals, and so be able to inoculate man with a mild form of tuberculous disease, which, theoretically, might prove to be preventive of other attacks of the same kinds. The experiments on the inoculation of syphilis will be in the memory of all of us. The virus had not been reduced by culture, or by passing it through other animals, and it is the opinion of Hutchinson and others that syphilis is not transmissible beyond the third generation. It is a well-known theory of vaccinia that that disease is only variola modi-

fied by passing through the system of the cow. We dare not indulge fanciful speculations on the subject, but that there is a future possibly productive of great practical results few can doubt.

The prevention of contagion, by declining to group consumptive people together in large numbers, is one of great national importance. There is no country which has built so large a hospital for consumption as we have. I have stated my own convictions on the question of contagion by personal contact in the ordinary way; but I have always upheld that phthisis would be better treated in separate dwellings, if possible in the country, rather than in cities, on dry soil, and on elevated localities. There can be no excuse for the grouping together of so many persons suffering from one disease, and that, too, productive of copious discharges from the air-passages, except that of convenience. Convenience for treating numbers together implies economy of money and of skill, and of all the appliances for the care of the sick. While acknowledging the necessity, we should exercise the greatest care in ventilation, cleanliness, the frequent removal of sputa, and of what is not often sufficiently attended to—the renewal of underclothing of the sick. Dust should never be allowed to accumulate, and the air-passages of the building should be frequently examined and cleansed.

I have stated the evidence obtainable as to whether the Brompton Hospital has been a spreader of consumption, and I must leave each to form his own conclusions. In doing so two things are to be remembered:—First, that great cleanliness has been always practiced; and next, that when the ventilation went wrong the outbreak of sickness which followed was septic, not tubercular. In treating the stage of phthisis in which lung disorganization is taking place, and according to the new theory a number of material germs are set free and find their way into the blood and lymphatics, there can be no reason why a fair use of antiseptics should not be practiced. The germ-destroying properties of many chemicals are now known; but we are yet in the infancy of efficient modes of applying them. Inhalations as now practiced are only made use of for short periods; but a long continued exposure of the air-passages to various vapors capable of being inhaled should surely be had recourse to. Not only should inhalers be used which may alter the septic character of the secretions, but to give the system a fair trial, the patient should be placed in a chamber impregnated with certain vapors, as carbolic acid, sulphurous acid, iodoform, and such like, and allowed to remain for hours exposed to their influence. In the new building at Brompton we have had such chambers constructed, and I trust we may shortly hear details of the results. By all the later theorists the local treatment of the lung has been brought into prominence, and there are other considerations besides the use of antiseptic or germ-destroying local applications which need further investigation. Such are the conditions of altered pressure to which the lung may be subjected. The collapse of its cells may thus be obviated, and the expansion and increased vital energy of alveoli bordering on those already blocked or injured may be promoted. We seem to have been waiting too helplessly for something to guide our treatment before having recourse to methods of altering pressure and increasing the vitality of tissues, of correcting foul secretions or stimulating languid and devitalized products of diseased action, which the surgeon daily applies to outward wounds with advantage, and frequently with success. In the new Brompton Hospital there are air chambers to which diminished or increased

pressure can be applied. The results hitherto published at other places have been limited and perhaps somewhat empirical, but no doubt time will develop correct opinions on this important question. We already know that the contraction and even ultimate closure of the cavities in the lung greatly depend on the condition of the surrounding lung tissues, and especially of the neighboring alveoli. That which Dr. Ewart has called compensatory hypertrophy, and which supplies mechanical extension of the healthy parts of the lung, acts both by improving the general condition of the system by affording more respiratory space, and also by pressure on the cavity walls. The boundary zone of a cavity may be more or less consolidated by fibrous alterations, by pneumonic deposits, and by pleural thickening. It is impervious and tough, and but little vascular. If a cavity were not so surrounded, its collapse and cure would in many instances follow a suspension of the morbid events of which it is the seat—purulent infective secretions, not unfrequently charged with bacilli. The effects of altered atmospheric pressure may be found of the greatest use in furthering the processes of dwindling and contraction.

Let us very briefly consider this cavity stage of phthisis. The possibility of the healing may be regarded as proved. Hertler, of Vienna, in 1880, had collected 780 cases in which cavity of the lung had become obsolescent, and in several of these complete cicatrization had taken place. There is no doubt that the physical signs of cavity often disappear, although it is likely that this is due rather to collapse than to obliteration. First, the reparative change appears to be governed by the cessation of morbid action and the disappearance of bacilli, and the lessened secretion in the cavity itself; secondly, by the facility with which its contents can be emptied into a neighboring bronchus; thirdly, by the mechanical conditions of its situation, and the state of the surrounding tissues. Apex cavities are unfavorably placed for contraction, owing to the surrounding thickening and adhesion of the pleura, through which the resistance of the ribs is conveyed. They are also by position removed from the closing up influence of pressure from the surrounding alveoli becoming enlarged; so that compensatory hypertrophy is not available. Nevertheless, deducting these mechanical difficulties in the way of closure, there is no reason to doubt that morbid actions may be sufficiently arrested in a cavity to permit of its healing. If these conditions are due to bacilli, they are then more locally within reach than in the earlier stages, when they are embedded in a tubercular nodule or in the walls of the alveoli. If the conditions are those of simple chronic abscess, whose contents may become putrid by the access of septic germs from the atmosphere, they are again accessible to remedies of the antiseptic class directly applied. If an ordinary wound be capable of setting up septic actions by exposure to the atmosphere, surely the lung cavity is equally if not more exposed, and should be guarded and treated in a like manner to that in which a surgeon acts towards an external abscess. As a matter of fact, septic phenomena are by no means an infrequent sequence of lung cavities, and are shown in secondary and distant pyæmic deposits. Therefore we should strongly advocate the local medication of cavities in the lung by direct antiseptic, stimulant, and other treatment calculated to kill parasites and restore a healthy state of secretion.

The surgical treatment of certain cavities by tapping has been practiced in this and other countries with a considerable amount of success. The ordinary apex cavity, with a free opening into a

bronchus, and with moderate daily secretion, not of a fetid character, is not likely to be much benefited by tapping, as, for the mechanical reasons we have given, it is not easy for it to collapse and become closed, the adhesions and condition of the surrounding parts of the lung forbidding such results. On the other hand, cavities with a less free opening into a bronchus and situated near the middle or base of the lung possess characters which do not forbid their relief, nor even their closure. Their secretion is apt to accumulate from gravitation having to find its way upwards into a bronchus, and fetor ensues, the cavity being never fully emptied. The mechanical difficulty is here considerable, as the secretions must be projected upwards, and the surrounding tissue of the lung, generally indurated, cannot contract on its contents. In phthisis a large proportion of the expectoration comes from bronchial irritation, the lining membranes of the tubes, in the neighborhood of such cavities, being irritated by the passage of fetid secretions over it. It is often found stripped of its epithelium, and even ulcerated in the neighborhood of the cavity, conditions which can never be remedied so long as the bronchial tube is the only exit for foul discharges. It is most natural to apply surgical principles to such cases, and by a free drainage to carry off septic matters. I may briefly allude to the conditions requisite to justify operation. The signs of cavity should be unmistakable and should all be present. And the existence of adhesions of the lung to the pleura should be proved at the point at which it is proposed to operate. In acute gangrenous cases, or hæmorrhagic cases where the lung is in a vascular spongy state, where little fibroid change has taken place, and adhesions of the pleura are not evident, the operation should not be performed; the trocar would not enter a defined cavity, but a broken up lung and hæmorrhage must occur, or the contents might escape into the pleura. But there are many cases met with in practice where tapping may prove highly beneficial and prolong life, by lessening copious suppurations, by altering the fetid character of the discharges and so relieving fever and preventing septic infection. I have witnessed several such cases, and there are a considerable number on record.

After the review which we have taken of the various forms and assumed causes of phthisis, we can have little hesitation in laying down one or two axioms to guide us in selecting the most suitable climate in which persons may reside who are either threatened with phthisis or inherit a proclivity to be counteracted. It should undoubtedly be of the bracing character, dry in soil and elevated. Starting from the supposition that a vulnerability is to be counteracted, which the best observers consider to consist in feeble circulation and tendency to stagnation and the pulmonary changes, and an undrained condition of the lymphatic system, which may give rise to exudations of low vitality, we ought to prescribe exercises and air, which give tone to the vessels. The whole state appears to be passive, a stagnation, a lowness, a want of contractile power in tissues, and this is not to be encouraged by placing its subject in relaxing heats, or permitting him to neglect exercise in fresh air of invigorating degrees. There is no doubt that the plan has been overdone by exporting such persons to a rigorous climate, but there is a just medium from which the benefits of pure and bracing air may be obtained without exposure to severities, for which these delicate frames and feeble circulations are not adapted by either their nerve power or the tone of their blood-vessels. It is also to be remembered that hæmoptysis is more frequent, and often to a dangerous

extent, on these Alpine heights; and it is evident that persons liable to such congestions should not reside there. The purity of air and constant change of a sea voyage are often preferable for invigorating purposes to a residence in winter in "upland valleys," where most of the day must be passed in poorly furnished apartments artificially heated by stoves.

In the stage of cavity, if it be single, and if febrile symptoms be absent, I have observed most benefit from a frequent change of locality, and from being much in the open air, if possible on horseback. The best reason for selecting a southern climate is undoubtedly that it affords facilities for open-air exercise. In searching for it, unfortunately, invalids have to travel far, for there is not much of a fixed and stable character to be found on this side of the Mediterranean. On reviewing the cases I have met with in practice, I find that those which survived longest were persons who travelled about in moderate climates and who, some of them, led a rough life occasionally in our colonies or in South America. A rule for our guidance, which I have always insisted on, I may be pardoned repeating here. Patients with a high temperature should not be advised or permitted to travel far, and those with much fever should not be moved at all. I care not whether the local disorder be inflammatory, or tubercular, or parasitic; that which is proceeding in the lung is an active condition of irritation, the blood is loaded with inflammatory products or bacilli, and rest is indicated before all things.

Let me say a word for those unblest by riches who are unable to travel for their health, who either have not the funds or decline to be a burden to richer friends, or to spend the last penny which may be wrung from the necessities of wife or children in a pursuit of health in a distant land. Well, I have had a great deal to do with the poor in this country, and I may console many by saying how well I have found numbers of patients go on in London—in London under the unfavorable conditions of climate so well known to all of us. I believe I was one of the first to note the great longevity of many cases of phthisis, and my statistics were gathered in the out-patient department of Brompton Hospital.

I had proposed to consider the use of nutrients in the treatment of phthisis, but time warns me that I must omit more than the bare mention of the fact that no parasitic theory can lessen the importance of the use of tonics and cod-liver oil. I must also apologize for the omission of a more detailed account of germicides. I would just remark that supposing we possessed a local remedy of sufficient power to ensure the destruction of such bacilli as are met with in the secretions, their rapid reproduction would soon overtake our treatment. I fear that in this direction we may have much empiricism and many disappointments.

Finally, to sum up the brief review which we have been able to make of these new doctrines, it would appear that while some facts, such as the presence of bacilli in all cases of phthisis and their absence in other affections of the lungs and air-passages, are fully proved, there are some assertions of those who hold that such appearances in the lungs and its secretions are the proximate and invariable cause of the disease, which we must for the present hold to be *sub judice*. Among these doubtful theories are those which concern the production of the parasites. Whether they be endogenous or introduced from without, whether they may not find their birth in certain blood changes which are the outcome of pyrexial action in the system, or whether they are the product of a like morbid condition in other animal bodies, and from them

introduced into other organisms by contact or infection, must remain for the investigation of later pathology. We may safely relegate these interesting questions to the ardent students who are now everywhere carrying on new observations. And for ourselves, knowing well that all pathology is progressive, and that we see but a portion of truth at any time, be content to await the result.

Lumleian Lectures

ON

URIC ACID: ITS PHYSIOLOGY AND ITS RELATION TO RENAL CALCULI AND GRAVEL.

Delivered before the Royal College of Physicians,

By A. B. GARROD, M.D., F.R.S., F.R.C.P., etc.,

Consulting Physician to King's College Hospital.

LECTURE III.

MR. PRESIDENT AND GENTLEMEN—Before proceeding to the more purely therapeutic part of our subject, I must devote a few minutes to the discussion of other classes of food in reference to the uric-acid-secreting function; and, first, with respect to the influence of a nitrogenized, and especially of an animal diet. Observations are not wanting to show the effects of a pure meat diet on the urine. Those of Lehmann are perhaps the most satisfactory. He first determined the daily excretion of the principal constituents of his urine when on an ordinary mixed diet; he then placed himself on a purely animal diet (chiefly eggs) for twelve days; afterwards, for another twelve days, on a purely vegetable diet; and subsequently, for two days, on a purely non-nitrogenized diet, which consisted of fat, milk, sugar, and starch. His conclusions are that the total solids, as well as the urea, are much increased by animal food, while they are considerably decreased by a vegetable diet, and still more so by one which is non-nitrogenized; whereas the uric acid is not nearly so much affected by the nature of the food, provided that it contains nitrogen. Thus the urea, on an animal diet, was to the uric acid 53.198 : 1.478; on a vegetable diet, 22.481 : 1.021; and on a mixed diet, 32.498 : 1.183. He found that after the use of purely animal food the urine of man closely resembles that of the carnivorous mammals, becoming of a light amber-color, having a strong acid reaction, and containing neither lactic nor hippuric acid. On the other hand, after a course of vegetable food, the urine becomes of a brownish-red tint, is much less acid, often deposits the earthy phosphates, and always contains alkaline lactates with oxalate of calcium; in fact, the urine closely approaches to that of the herbivorous mammal.

As a result of all the experiments made by different observers, both on man and the lower animals, I think we may fairly conclude that meat, taken in such quantities only as are sufficient to keep up the nutrition of the body, has no tendency to increase the excretion of uric acid; that, when the diet is purely animal, but the quantity small, the uric acid, far from being large, becomes exceedingly small in amount, more especially when it is compared with the urea. On the other hand, that the taking of a great quantity of meat—an excess compared with the requirements of the system—tends to increase the uric acid, though,

even then, not more than in proportion to the urea.

These different facts can be advantageously applied in practice in the treatment of gravel and calculus. In such cases, there is certainly no reason why a proper quantity of animal food should not be taken; and the knowledge of this is important, seeing that many patients have been lowered in health by being kept on insufficient diet, with the idea that by these means a lessening of the excretion of uric acid would result.

Causes of Gravel and Calculi.—In the course of our experience most of us have noticed that there are certain individuals who are prone, either to pass a urine thick from urates, or containing uric gravel, or to void numerous small calculi. I think we shall find, on inquiry into the history of those liable to pass gravel and calculi, that they frequently inherit gout. In looking over 1,900 cases of this disease, which I have had extracted from my books, I find it mentioned that, of this number, comparatively few had passed calculi. If, on the other hand, we examine cases of calculus, we shall find that a much greater percentage of these patients are the children or grandchildren of gouty parents. In the course of my experience, it has frequently occurred to me to see a man suffering from gout, and to find that he has one child who has had attacks of joint-gout, another who is suffering from eczema, and a third who is passing uric gravel or calculi. It is not very uncommon to find articular gout and calculus present in the same person; in fact, we may fairly conclude that those who suffer from an abnormal condition of the uric acid function on the inner side of our imaginary partition, mentioned in the first lecture—that is, in the blood or system at large—are also more prone than others to experience the effects of a morbid state of the same function on the outer side, or in the urinary tract; in other words, gouty subjects, or those who inherit that diathesis, are more liable than others to gravel and calculus.

There are, however, many influences which act strongly in determining the morbid action to the urinary tract—influences which will often cause the occurrence of such troubles in those who do not inherit them. We see, for example, that in England stone is more common in some counties than in others, and at one time of life more than at another. How can we account for this? Anything that checks the cutaneous function, such as the cold east winds of spring, felt so acutely in Suffolk and Norfolk, appears to act as an exciting cause, and it is well known that in these counties gravel and calculus are very common. When the action of the skin is checked, there is no increase of urates, but an undue acidity of the urine, which leads to the precipitation of the uric acid. Cold alone is not necessarily a cause, for in Sweden and Norway calculous diseases are very rare. Another cause which, I believe, leads both to an increase of the excreted uric acid and to its deposition in the urinary organs, is portal congestion. Of the exact pathology of this we are at present ignorant, but in the prophylactic treatment of gravel and calculus, it is important to look to this point; and much good is produced by the frequent use of remedies which tend to relieve such a condition. Hence the value of Carlsbad waters and salts, and of the numerous saline purgative waters which, of late years, have been so much employed. It must always be borne in mind that, in this administration in the diluted form, the water itself becomes an important element in their action upon the system.

Fatty and Oleaginous Food.—With regard to the influence of such food on the urinary excretion, the experiments of Dr. Böcker seem to be most

trustworthy; and from them it would appear that no influence whatever is exerted on the excretion of water, urea, uric acid, or any other constituent of the urine, by taking from about a quarter of an ounce to three ounces of butter daily.

Effects of Water on Gravel and Calculus.—Many observations have been made on the effect of increasing and diminishing the quantity of water taken with food or when fasting. In the latter case, especially if the water does not pass off by the intestines, it causes the urine to become pale and copious; but, at the same time the action of the skin is augmented. It has been asserted that the amount of uric acid is lessened, but it is doubtful whether this is really the case; but any increase in the quantity of the urine helps to keep this principle in solution, and may thus mask its presence.

When the quantity of water taken with food is increased, it appears that certain of the urinary principles are augmented in amount, owing probably to the increased metabolism of the tissues; but, at the same time, it is stated that the uric acid is decreased. Further observations are much required before we can come to any accurate conclusions on this point. That the quantity of water passed by the kidneys in a given time has a great influence upon the physical condition of the urine is evident. If, for example, a healthy man during one day passes an ordinary quantity of urine, and during a second day but half the amount, it is probable that, on the latter occasion, the urine will be turbid and thick from the precipitation of urate of sodium, whilst the first day's urine will remain bright and limpid; and yet the daily elimination of uric acid may be the same on both occasions, and it only requires that an equal quantity of water should be added to the concentrated urine to bring it to the same condition as the more limpid specimen. If a patient continues day by day to pass urine so concentrated that it rapidly becomes thick, perhaps even in the bladder itself, a very slight change in the acidity of the fluid will cause uric acid to be set free and crystallization to take place, and then uric gravel, in the shape of Cayenne pepper deposit is formed.

If these changes only ensue after the urine has been passed, of course, it is of no real consequence; but if they take place while the urine is still within the urinary organs, then either free acid or some urate may become deposited and form gravel, or increase the size of any calculus already existing within the urinary passages. The deposition of uric gravel is of very common occurrence in children; and I know, from clinical experience, that this often depends on the deficient amount of water excreted. I will give one instance of this.

A little boy, five and a half years old was passing, from day to day, urine which either contained uric acid crystals or gave rise to a copious red sediment almost immediately after it was voided; his health was otherwise good. I had the urine of the twenty-four hours carefully collected, and found that it amounted to sixteen fluid ounces, with a specific gravity of 1031. On causing the child to take five fluid ounces of water an hour before breakfast, and the same before his late afternoon meal, the quantity of urine was brought up to twenty-four fluid ounces, and the specific gravity reduced to 1017, nor could any uric acid be discovered when the fluid had stood for thirty-eight hours from the time when the last portion was passed. In a few days the quantity of urine was increased to thirty-seven fluid ounces, and the specific gravity lowered to 1013.

In many cases it is only necessary to give simple water, such as is usually supplied for drinking purposes. The importance of the proper adminis-

tration of simple water in these cases as a part of the diet is the greater seeing that the plan of treatment can be pursued for an indefinite period; whereas the duration of a course of mineral waters is necessarily limited to a few weeks. I believe that as yet the medical profession have not laid sufficient stress on the proper administration of water in the treatment of gravel and calculous diseases.

Effects of Alkaline Treatment.—In the treatment of uric gravel and calculus the different alkalies and their salts play a most important part. If we give any fixed alkali in the state of a carbonate, it is, we know, absorbed, and passes through the kidneys in an unaltered form—that is, a carbonate, when taken by the mouth, appears as such in the urine, and, therefore, necessarily diminishes the acidity of that fluid, sometimes rendering it neutral or even alkaline, according to the quantity administered; so that if we give, at frequent intervals throughout the day, a quantity of the alkali equal to the neutralization of about thirty grains of oxalic acid—the average acidity of the day's urine—we shall, as a rule, keep that fluid in a neutral state.

In considering the equivalents of the different alkaline metals whose salts are employed in medicine, we find that the neutralizing power for acids of the different bases must vary considerably. The most practical method of estimating this power is to measure the different alkaline metals, in the form of their carbonates, against each other, when we find that seventy-four parts of carbonate of lithium equal eighty-four parts of carbonate of calcium (chalk or its congeners), 106 parts of carbonate of sodium, and as much as 138 parts of carbonate of potassium. It must, however, be remembered that it is not merely the neutralizing power for acids of the above compounds that has to be considered in treating of uric acid disorders; we must also look at the character of the salts which result from the combination of the acid with the metal, for some urates are very much more soluble than others.

It is a matter of clinical experience that lead-impregnation powerfully disposes to the production of gout; and I can also assert, as a result of long-continued observation, that iron salts have a considerable tendency to cause a recurrence of an attack when administered, as they often are, with a view to overcoming debility.

The difference of solubility in the alkaline urates forms a subject of great interest, for the value of a solvent may often be expressed correctly as the product of its neutralizing power plus the solubility of the resulting salt. Let us take, for example, carbonate of sodium. It has been shown that its neutralizing power is large compared with carbonate of potassium, 106 parts of the former doing the work of 138 parts of the latter; but, on looking at the table of solubilities, it is seen that the soda salt has less than half the solubility of the potash salt. The same remark applies to carbonate of magnesium, as, although it possesses great neutralizing power, the resulting salt is very little soluble, and the very sparing solubility of the lime salt renders its employment as a solvent of uric acid undesirable.

The other properties of the alkaline salts must also be taken into consideration when they are administered as remedies. On comparing a soda salt with a corresponding potash salt, it is found that the latter is more prone to produce diuresis than the former; at the same time, there is good evidence that the alimentary canal and its appendages, especially the liver, are more influenced by soda than by potash. This is what might naturally be expected, seeing that true bile consists

essentially of glycocholate and taurocholate of sodium. Magnesia salts act more or less as purgatives, and lime salts as astringents, but all act as neutralizers of acidity, and to some extent as solvents of uric acid. Gravel and calculi usually consist of free uric acid, and even the least soluble of the urates, omitting lead and iron, are much more soluble than uric acid itself.

There is one alkali—lithia—which will require some few minutes' consideration, and upon which I propose to bring forward several new observations and experiments; but, before proceeding to discuss its value, I may make some remarks on the different salts of the alkalies, some of which are more eligible for exhibition, especially in the treatment of gravel, than the carbonates.

All of us are probably aware that, if an alkaline citrate is given by the stomach, it is changed, either in the blood or kidneys, into the corresponding carbonate. The same is the case when an acetate or tartrate is administered; in fact, most of the vegetable salts are thus decomposed in the system, carbonates appearing in the urine. The establishment of this point is important, inasmuch as we can, by the use of these valuable salts, introduce into the system, through the mouth, salts which have no alkaline action on the stomach and form, often, an important part of vegetable food, and can still produce the remote alkaline influence where it is wanted; in short, we can often give even an acid salt, grateful and useful to the stomach, and yet have the very opposite effect induced upon the urine.

I will now draw your attention to the salts of lithia, which were first introduced as remedies by myself as far back as 1859. If we look to the atomic weight of the metal lithium we find it very low, only 7. The number representing the carbonate of lithium is also small; compared with carbonate of potassium it is as 74 to 138; hence the neutralizing power for acids possessed by carbonate of lithium is greater than that of carbonate of potassium in the above proportions. The acid urate of lithium requires only 220 parts of water at the body temperature to dissolve it; the corresponding potash salt requiring 500 parts, and the soda salt as much as 1130 parts, while the magnesia and lime urates take 1,600 and 2,800 parts respectively; so that, with respect both to neutralizing power and solubility the lithia carbonate has a great advantage over the corresponding salts of potash, soda, magnesia, and lime.

In a paper in the *Medico-Chirurgical Society's Transactions*, vol. xlviii., 1875, on "The Solvent Treatment of Urinary Calculi," Dr. William Roberts, of Manchester, came to the conclusion that potash carbonate dissolves uric acid more rapidly than the soda salt. This he ascertained by placing sections of uric acid calculi in phials, and causing currents of the different solutions, at blood heat, to pass over them at a regulated rate. He also found that the strength of the solution employed was of much importance, the greatest amount of solvent power being exhibited in solutions containing from forty to sixty grains of the alkaline carbonate to the imperial pint (twenty fluid ounces). Below this strength the power of the solutions gradually declined, until, with those which contained less than three grains to the pint, the solvent power scarcely exceeded that of water. On the other hand, if the strength was above sixty grains to the pint, the pieces of the calculus became encrusted with the alkaline bi-urates which were then deposited, and thus the further action of the solution was impeded. This was especially noticeable when the strength of the solutions was much above 100 grains to the pint. Even without the actual experiment with pieces of uric calculi,

I think we could predict that potash would prove a more powerful solvent than soda; for we have only to glance at the table to see that urate of potassium requires, at the body temperature, only 500 parts of water to dissolve it, whereas the corresponding soda salt takes as much as 1,130 parts. The soda salt certainly has an advantage in its greater neutralizing power, but not sufficient to make up for the far less solubility of the resulting urate. In the paper referred to, and in his book on "Urinary and Renal Diseases," Dr. Roberts has the following footnote: "Some experiments were also made with carbonate of lithia, which has been vaunted in recent times as a solvent for uric acid. Its power was found much inferior to that of carbonate of potash and soda. Its reputation seems to have been gained through its comparative insolubility. Only weak solutions of it could be employed." I refer to this passage because other authors have evidently been influenced by the statement; for example, Sir Henry Thompson, in his little work on "The Preventive Treatment of Calculus Disease," says: "Dr. Roberts finds carbonate of potash to be the most powerful solvent; better than soda, much better than lithia."

I have recently had a series of experiments made, the results of which are seen in the following table:—

Effects of Solutions of Carbonates of Sodium, Potassium, and Lithium, upon Fragments of Uric Acid Calculi.

Strength: 60 grains to 20 fluid ounces. Temp., 100° F. Time of action, 12 hours.

In nine experiments (three with each carbonate) the solvent powers were as follows:—

With Carbonate of Sodium:

21·2—18·1—15·3 per cent.
Mean = 18·2 per cent.

With Carbonate of Potassium:

28·6—27·6—38·3 per cent.
Mean = 30·5 per cent.

With Carbonate of Lithium:

43·8—58·6—47·7 per cent.
Mean = 50·0 per cent.

In three experiments. Strength of solutions, 50 grains to 20 fluid ounces. Time, 12 hours. Temp., 100° F.

With carbonate of sodium... 16·2 per cent.

With carbonate of potassium 23·1 "

With carbonate of lithium... 37·7 "

One experiment, using carbonate of lithium—100 grains to 20 fluid ounces. Solvent power—70·2 per cent.

Two experiments, using carbonate of potassium and lithium, 20 grains to the 20 fluid ounces.

With carbonate of potassium 21·2 per cent.

With carbonate of lithium... 33·1 "

Two experiments, using carbonate of potassium and lithium, 10 grains to the 20 fluid ounces.

With carbonate of potassium 11·2 per cent.

With carbonate of lithium... 17·5 "

The substance employed was a large uric acid calculus given to me by my friend Mr. Erichsen. It was first cut, to ascertain its internal structure, and to see if this was pretty uniform throughout; then a portion was broken up, and the fragments washed with distilled water, and carefully dried. About equal weights of the calculus were put into

three bottles, and solutions of neutral carbonates of sodium, potassium, and lithium were added to them. The solutions were of the strength of sixty grains to the twenty fluid ounces; the action upon the calculus continued for twelve hours, at the temperature of 100° Fahr., with frequent agitation. Separate quantities of the calculus were taken. One was first treated with the lithia solution, then with those of potash and soda; another was treated first with the potash solution, then with those of soda and lithia; a third with the three solutions in the order, soda, lithia, and potash. The quantity of the solution used in each case was the same. The results of these experiments are very striking. Let us first consider the soda numbers; we find that the percentage of solvent power in the three experiments was 21·2, 18·1, and 15·3, the average being 18·2 per cent. The percentage of the potash numbers was 28·6, 27·6, and 38·3, the average being 30·5 per cent. The corresponding lithia numbers were 43·8, 58·6, and 47·7, the average being 50·0 per cent. We see, then, that in solutions of the strength mentioned the value of the lithia salt over that of potash, and still more over that of soda, is most evident. Other experiments were afterwards made with solutions of different strengths. Thus, in three experiments, the solutions contained fifty grains to the twenty fluid ounces. Time, twelve hours; temperature 100 Fahr.; with frequent agitation. The carbonate of sodium solution dissolved 16·2 per cent., the carbonate of potassium solution dissolved 23·1 per cent., and the carbonate of lithium solution dissolved 37·7 per cent.

In another experiment, the sixty grain lithia solution being used, but the time altered, at first to ten hours at 100° Fahr., then to eight hours at about 60° Fahr., the solvent power was 60·8 per cent.; but when a solution containing one hundred grains to the twenty fluid ounces was employed, the solvent power was as high as 70·2 per cent.

Lastly, it will be observed that, when the comparison of the solvent power was made between the potash and lithia salts, using twenty and afterwards ten grains to the pint—the quantity used by Dr. Roberts in his lithia experiments—the results were in each case more than 50 per cent. in favor of the carbonate of lithium.

It will be seen from these experiments that so far as soda and potash are concerned the results obtained exactly agree with those of Dr. Roberts; they exemplify the greater solvent power of the latter over the former, a result which might have been clearly anticipated, but, on the other hand, they are totally opposed to his conclusions with respect to lithia. How is this to be explained? On looking at the solubility of urate of lithium we find it more than twice that of the potash salt, or as 220 to 500, and we can scarcely believe that in solutions of the two carbonates the uric acid would be found to be most soluble in the one which contained the alkali which gave the more insoluble urate; this would be absurd—in fact, we should anticipate that the lithia solution would prove as superior to the potash as we have already found the potash to be to the soda solution.

We must look for some means of explanation. Dr. Roberts used the expression "only weak solutions of carbonate of lithia could be employed," italicizing the word "could;" and he appears to have used in his four experiments, two of which are given in the Medico-Chirurgical Society's Transactions, solutions of the strength of ten and twenty grains to the twenty ounces, whereas, in the case of the potash, he found that a sixty grain solution is the most powerful. Now it will be seen in the table that solutions of carbonate of lithium were employed containing sixty and even as much as 100 grains to the imperial pint, and

that, in the case of lithia, as the strength was increased the solvent power also was augmented. I should imagine that Dr. Roberts either used an impure carbonate of lithium or assumed that only one grain was soluble in the fluid ounce, as he used only ten and twenty grain solutions; whereas as much as 100 grains can be dissolved, at the temperature of the body, in the imperial pint of water. Impurity of the salt and the use of solutions which were far too weak will at once explain the discrepancies and the cause of the erroneous statements with regard to the solvent power of the lithia salts. The inevitable conclusion, therefore, is this: that lithia salts are far more powerful solvents of uric acid than potash salts, while these latter are more efficacious than those of soda. We have only to take three small phials, filled with a solution of the three carbonates, of the same strength, and to put into each the same quantity of small uric calculi, the amount being such that the lithia will dissolve them. If we carry these in a warm pocket, after a short time it will be seen that all the calculi have disappeared from the lithia solution, while more than half are left undissolved by the potash, and about four-fifths by the soda solution.

I have been informed by some patients that they have been deterred from using lithia salts, although they had found them valuable, by having been told that their employment would prove injurious, owing to their caustic effects upon the renal organs. In answer to this objection I may say that I have found the action of carbonate of lithium to possess less destructive power than the corresponding salts of potash and soda upon animal tissues.

The only effect that I have ever noticed has been that, when the quantity is increased beyond a certain amount, a little tremor of the hands is produced, which passes off at once on the diminution or omission of the dose of the salt. I have known patients of their own accord, continue the use of lithia salts for more than ten years, with the effect of entirely preventing the recurrence of the symptoms to remove which they were first prescribed, and without the production of any injurious effect. For myself, I have not the least doubt as to the value of lithia salts as therapeutic agents, and am convinced that, by their employment, depositions of uric acid in the renal organs can to a large extent be prevented. Free dilution and administration on a fasting stomach are points of much importance, which should be attended to in the administration of alkaline remedies. I have been much in the habit of using potash with lithia, in the form of the citrate or the carbonate; the former to give neutralizing, the latter to increase the solvent power.

I do not believe in the value of any injections into the bladder in the treatment of vesical calculus; at the very best, the process must be most tedious; and at the present day, when the surgery of the subject has reached to such great perfection, when a calculus can often be removed completely from the bladder in a few minutes without the use of the knife, I cannot but think that the surgeon is better qualified for the treatment of such cases than the physician.

Influence of Hippuric and Benzoic Acids.—Before proceeding further with the treatment of gravel and calculus, I must redeem my promise to explain certain difficulties in the physiology of uric acid which had to be passed over in my first lecture. How is it that the urine of the sucking calf contains a notable quantity of uric acid, seeing that the same animal, when it grows up and takes its ordinary food, excretes urine which is devoid of this principle? Why should the simple altera-

tion of food cause such a result if uric acid is formed in the kidneys themselves? Is not this fact completely opposed to the second view? Before endeavoring to explain these difficulties I thought it desirable to prove the fact, and examined first the urine of two sucking calves. In both I found distinct evidence of the presence of uric acid. At the same time I discovered another previously unknown fact—viz., that the cow's urine also, under certain circumstances, contains uric acid, as when taking turnips, mangold, brewers' grains, and such-like food, with little hay or grass, and that with such a diet there is little hippuric acid in it. In the horse's urine, which was rich in hippuric acid, I found no uric acid. At first sight it would appear to follow from these various facts that the seat of origin of uric acid is further back than the kidneys, and that these organs merely eliminate it from the circulating fluid; but I have already shown that the kidneys will not act as filterers of uric acid, even when that principle is known to exist in the blood.

Some little time ago I arrived at the idea that if the urine of man could be maintained in a condition resembling that of the herbivorous mammal, uric concretions, uric gravel, and calculus would be unknown. Alkaline remedies, useful though they are, do not effect all that could be desired. They do, indeed, as we have seen, hold the uric acid in solution, but in no degree do they remove it. While following up my idea of assimilating the urine of man to that of the herbivorous mammal, I made several experiments. I took a specimen of healthy human urine, of full specific gravity, and sufficiently rich in urates to give a free deposit of uric acid crystals when acidulated. With this I filled two tubes to about one-fourth of their capacity. To the first of these I added the urine of a horse, so as almost to fill the tube; to the second I added the same quantity of distilled water, in order that the amount of dilution of the human urine should be the same in each tube. After the tubes had been kept for some two or three hours at about 100° F., their contents were examined. A few drops of hydrochloric acid added to the second tube—where water had been used as the diluent—caused a slow crystallization of uric acid, but the acidification of the first, in which the urine had been diluted with that of the horse, failed to exhibit any precipitation; nor, when it was evaporated to a small bulk, could uric acid be detected either by the murexide or any other test. The experiment was repeated with the substitution of the urine of the lion for that of the horse. This failed to cause the disappearance of the uric acid.

If these observations are correct, we have found not only that the horse's urine is itself free from uric acid, but that it possesses the power of destroying, at least to some extent, the uric acid contained in the urine of man. It struck me that this conclusion was one which might be fraught with weighty consequences, and demanded much further investigation to corroborate it. Such proof is not wanting.

I next took eight very small uric acid calculi, none of them larger than a pin's head, and, by the aid of a solution of carbonate of lithium, dissolved them in a little water. To this solution I added about eight ounces of the urine of the horse. After the mixed fluids had been kept some few hours at the temperature of the body, no uric acid could be detected. This experiment shows that uric acid, in the form of calculi, when first dissolved in an alkaline solution, is destroyed by the influence of some ingredient which is present in the urine of the horse.

After reflecting upon these phenomena, I endeavored to find out what was the principle con-

tained in these urines of the herbivora which imparted to them this peculiar power; and, seeing that they are rich in hippuric acid—a substance absent from the urine of the carnivora—I instituted a very numerous set of experiments upon the action of this acid on uric acid. First, a strong solution of hippurate of potassium was mixed in equal quantities with a cold solution of the urate of the same metal, and kept for some few hours at the temperature of the body. On subsequent examination for uric acid by the microscopic test, none could be found, nor could any be detected by the murexide test. Another recorded observation is as follows: A cold concentrated solution of urate of ammonia was mixed with a strong solution of hippurate of sodium, made slightly alkaline with the carbonate; after being kept for a few hours at 100° F., no uric acid could be found. As it might be urged that the uric acid, though existing, was masked by the presence of other matters, the following observations were made, and have been frequently repeated. A cold solution of urate of ammonium was added to one of hippurate of sodium, and the solution made slightly alkaline with the carbonate, so as to imitate as nearly as possible the conditions which exist in the urine of the herbivora. On immediately placing a drop on a microscopic slide, and acidulating it with hydrochloric acid, numerous long crystals of hippuric acid were soon formed, and afterwards rhombic crystals of uric acid were seen, these latter being readily distinguished by their characteristic shape, and by their intense polarizing power for light. After about half an hour, the solution having been previously warmed up to the temperature of the body, a second drop was examined, and the uric acid crystals were found to be much less numerous, and in another hour or so they were not to be detected at all. The solution was afterwards evaporated, and no evidence of uric acid could be discovered either by the microscope or the murexide test. By this observation the fact that a change slowly takes place in the solution of the mixed salts is demonstrated; and it is also proved that the uric acid is not simply masked by the presence of other salts, for it is readily exhibited when the solutions are first mixed, and only slowly disappears under the influence of time and warmth.

In the earlier experiments which I made, which were qualitative only, it was found essential that the hippuric acid should be in large excess, in order that the results should be conclusive; but I was soon led to make numerous quantitative experiments.

In these observations I have used the urates of ammonium, sodium, potassium, and lithium, and acted upon them with the hippurates of the same bases, and I have uniformly found that when hippurates and urates are together in solution a change ensues, the urate becoming gradually destroyed, and probably a part of the hippurate also. It has required under the conditions which have been present in most of the experiments nearly fifty times as much hippurate as urate for the complete destruction of the urate; but when the dilution was much increased the quantity of hippurate required seemed to be lessened, as little as twenty-five parts of hippurate being sufficient. Possibly, in the animal body the action takes place more rapidly than in the flasks of the laboratory.

Having established the fact that hippuric acid reacts upon uric acid, we can, I think, at once make use of it to explain a difficulty which we left unsolved in our first lecture in relation to the urine of the sucking calf. We have only to take our original assumption that there are cells in the kidneys of all herbivorous mammals capable of

forming uric acid; then this principle would be always present in the urine unless it was subsequently removed; and having now shown that hippuric acid has a destructive power over uric acid, it follows that when the urine of a herbivorous mammal contains but little hippuric acid, then uric acid is present. This is the case in the sucking calf. When, however, the young animal ceases to take milk and lives on a diet of grass, clover, and the like, then the urine becomes rich in hippuric acid, and the uric acid disappears, being removed by the destructive influence of the hippuric acid.

The explanation I consider to be satisfactory, though it is one which I could not till recently have imagined to be correct. It is generally supposed that hippuric acid replaces uric acid—that is, is formed in its stead in the system. It does indeed replace it, though not, as is usually thought, by being formed, under certain circumstances, instead of it, but on account of its possessing the power of removing the uric acid after it has been produced in the renal cells. The explanation holds good equally with reference to the occasional presence of uric acid in the urine of the adult herbivorous mammal. Under their ordinary diet a certain amount of uric acid is always formed. Hippuric acid is also present in large quantities, sometimes as much as 1 to 1.5 per cent., in which case no uric acid can be discovered in the urine; but when these animals are made to eat food which fails to yield hippuric acid the uric acid remains intact, and hence it is that from time to time we hear of the presence of this principle in the urine of herbivorous mammals.

Now it follows necessarily that what happens in the case of these lower animals, applies also to man. If the quantity of hippuric acid becomes increased, the uric acid becomes diminished, and we are in a position to explain an observation made by Heller, who, in conjunction with a friend, first ascertained the quantity of uric acid which each excreted daily when under an ordinary diet; they then changed the character of their food—Heller living for a week on wheaten and rye bread—his friend on rye bread only, water being the sole drink of both. The uric acid soon began to diminish and to be replaced by hippuric acid, and at the end of the week a mere trace of uric acid was found in Heller's urine—none in that of his friend. During the next week, on an ordinary diet, the hippuric acid gradually diminished and the uric acid reappeared in the former quantities. Doubtless the character of the food, in these experiments, had a direct influence on the formation as well as on the destruction of the uric acid, for the amount of the nitrogenized elements of the food must have been small.

We know that glycine or glycooal (gelatine sugar), which enters into the composition of the bile of many animals, is closely connected with hippuric acid, that this latter can be broken up into benzoic acid and glycine, when boiled with caustic alkali, and, in fact, benzoic acid, when absorbed from the stomach, takes up glycine and becomes converted in the system into hippuric acid, and is thus thrown out in the urine. Such being the case, I thought it most desirable to try the influence of this body upon uric acid and to find out whether it plays any part in the change of the uric acid. I made numerous experiments, using glycine in place of hippuric acid, the other conditions remaining the same, and in no instance did I observe any change in the uric acid, even when days or weeks had elapsed. I then had to look to benzoic acid and ascertain whether the change in the uric acid was due to its influence, and for this purpose I completed a set of observa-

tions corresponding to those previously made with hippuric acid. The results were as follows:—I found that benzoic acid, in the form of a benzoate, when in contact with an urate in an alkaline solution, caused the same slow change in the uric acid which ensued when a hippurate was employed. This change, however, cannot be well observed under the microscope because the crystallization of the benzoic acid is so rapid that the presence of uric acid is obscured; but, when the solution is evaporated and the benzoic acid removed by alcohol, the murexide test can be readily employed.

To us, as physicians, several questions naturally suggest themselves. Can we make any practical use of the facts before us? Will the administration of hippurates or benzoates prove of any practical value in the treatment of the different forms of diseases connected with the uric acid diathesis? Can a diet be devised which will assimilate to some extent the urine of man to that of the herbivorous mammal? These are questions of no little importance to us and to humanity at large.

Let us see how far they may be answered. In January, 1842, when a young student, I read a paper before the Chemical Society, which was published in their Transactions and in the *Philosophical Magazine* for that year. It was entitled "On the Conversion of Benzoic Acid into Hippuric Acid in the Animal Economy." In it, I fully confirmed Wöhler's then recent discovery of the conversion of the one acid into the other, but I proved that this change could not be effected by the benzoic acid uniting with the uric acid, as had been suggested; first, because the quantity of the latter was not sufficient; secondly, because the uric acid found in the urine excreted three or four hours after the taking of benzoic acid was not very appreciably diminished. I also suggested in the paper the probable future synthesis of hippuric acid, and that, if benzoic acid be administered beyond a certain amount, the excess will pass into the urine in an unchanged condition. Both these suggestions have since then been realized. Within the last few years I have returned to the consideration of the subject, and have obtained a large amount of clinical experience.

If hippuric and benzoic acids in an alkaline solution possess the power of changing and removing uric acid it is natural to suppose that when the blood is in an abnormal state from its presence the administration of the salts of these acids should prove valuable; for there is no doubt that if hippurate of sodium be added to a blood-serum which shows the presence of a urate the latter is soon removed from it. It is important to ascertain whether they are of value in cases where uric acid is liable to be deposited in any portion of the urinary tract.

In the first place these salts act advantageously on the mucous membrane of the bladder and its appendages, and in cases where there is a disposition in the urine to become ammoniacal from decomposition they are most useful in checking such tendency. You will, perhaps, remember that in my first lecture I said that I had found the urine of the horse much less liable to decomposition than that of man—a circumstance possibly due in part to its containing hippuric acid. This action on the membrane may influence much the secretion of the colloid matter, and thus prove valuable in cases of gravel and calculus, which are so intimately associated with this colloid; and, lastly, it may have an effect upon the excretion of uric acid, a point which I must now endeavor to ascertain.

I have said that the usual absence of uric acid from the urine of the herbivorous mammal is due,

not to its non-formation, in small quantities in their kidneys, but to the presence of considerable quantities of hippuric acid in the urine; and that, provided that we remove this latter principle by an alteration in the food, assimilating it to that of the young sucking animal which takes milk only; or by giving vegetables which do not yield hippuric acid; that then uric acid appears in their urine. Ought we not, therefore, to conclude that the administration of benzoic or hippuric acid would influence the excretion of uric acid? In the herbivora the urine is always alkaline in reaction; in man it is acid. In my experiments on the destructive influence of hippuric or benzoic acid upon uric acid, I found it important to use solutions made alkaline with a carbonate, thus imitating, as nearly as possible, the condition of herbivorous urines. We do not get this in the case of man. In 1842, when, in a very limited number of experiments, I gave benzoic acid in the free state, I found but little alteration in the excreted uric acid, still it was lessened.

Kerner, who appears to have made a careful set of experiments, came to the conclusion that neither the nitrogenized nor the other principles of the urine were influenced by benzoic acid.

I have recently made some observations on the action of benzoic acid on the urine, with the results which I will give you in a minute. I may tell you that great care must be taken not to form conclusions from one or two experiments, as the excretion of uric acid is always fitful, little circumstances causing it to be greatly diminished for a few hours and then suddenly increased. If the uric acid is directly formed in the renal cells, it is natural to suppose that much of it would escape the action of the hippurates contained in the fluid portion of the urine, and especially if that fluid is in an acid condition; and experiments seem to confirm this idea.

I am still engaged in clinically investigating the value of the benzoates and hippurates, both in cases of gout and of gravel and calculus; and I hope ere long to bring the further results before the profession. I can confidently affirm that I have already obtained great advantage in the treatment of these diseases from their employment.

I frequently give the benzoic acid in the form of benzoate of sodium; but, if I wish at the same time to increase the quantity of the urinary excretion, then I give the benzoate of potassium or of lithium; and, if there be an abnormal acidity of the urine, some alkaline citrate.

Seeing that herbivorous animals excrete hippuric acid in a greater or lesser quantity according to the character of the food upon which they are fed, I cannot help thinking that some article of diet might be devised for those who suffer from the diseases above-mentioned, which might, at least to a great extent, keep in check the tendency to form and deposit uric acid.

In his report for February, Dr. Simpson, the medical officer of health for the City of Aberdeen, gives an instance of the way in which infectious disease is spread. A girl suffering from typhus fever was sent from Dundee to Aberdeen in a third-class railway carriage. The passengers in the same compartment, seeing how ill the girl was, kept the windows closed to exclude the cold air, and thus placed themselves in the most favorable position for contracting the disease, from which their fellow-traveller was, unknown to them, suffering.

The health of the troops in Egypt is showing continual improvement.

Lecture

ON

THE PRODUCTION, OUT OF THE BODY, OF PULMONARY SIGNS OBTAINED BY AUSCULTATION AND PERCUSSION.

By AUSTIN FLINT, M.D.,

Professor of the Principles and Practice of Medicine and of Clinical Medicine in the Bellevue Hospital Medical College of New York.

GENTLEMEN—In my lectures on Auscultation and Percussion given during the present session I have introduced illustrations of pulmonary signs produced either in lungs, healthy and diseased, after their removal from the body, or by imitating artificially the physical conditions which the signs represent. I have not heretofore appreciated the interest and value of such illustrations, as, in the first place, affording aid in becoming familiar with the differential characters of different signs; in the second place, corroborating the connection of cause and effect between the signs and certain physical conditions; and, in the third place, shedding light on the mechanism of the production of the signs. I propose in this lecture to give a *résumé* of the illustrations which my lectures have embraced. I am led to do this in order that you may be incited to repeat them at your leisure, and perhaps add to them others which may be equally or more interesting and instructive. We will consider first the signs obtained by percussion. The signs furnished by auscultation naturally arrange themselves into three groups—namely, respiratory sounds, adventitious sounds—or rales, and vocal sounds.

SIGNS OBTAINED BY PERCUSSION.

There are two articles which may serve to illustrate the normal vesicular resonance on percussion artificially—namely, a fine sponge of large size and a loaf of bread. These articles resemble the lungs in containing air within innumerable minute spaces. The distinctive characters of the normal vesicular resonance are due to the presence of air in the air vesicles or pulmonary alveoli. The characters which distinguish the resonance are lowness of pitch and a peculiar quality of sound called the vesicular quality. The resonance is variable as regards intensity, and therefore it derives no distinctive character from that source. Of the two articles named, the bread-loaf is much to be preferred. What is known as the "brick" loaf is best suited for the illustration. Covering the upper crust of the loaf with a napkin, folded once or twice, in order to diminish the noise produced by the contact of the fingers of the percussor, the resonance elicited by percussion has a pretty close resemblance to the resonance on percussing the healthy chest. Like the latter, it is low-pitched, and the quality is *sui generis*.

A bread-loaf may be made to illustrate *flatness*, *dulness*, *tympanitic resonance*, and the resonance which I have distinguished as *vesiculo-tympanitic*—the four signs obtained by percussion. Flatness is produced in a portion of the loaf by dipping it in water and allowing it to remain for a few moments. Up to the line on the loaf corresponding to the level of the water there is flatness. Above this line, for a little space, the interstices of the loaf being only filled in part with the water, there is dulness. In vesicular resonance flatness and dulness are thus illustrated in a single loaf. The highest pitch of dulness, as compared with the

vesicular resonance, will be found to be invariable. A still better plan is to immerse a part of a loaf in a solution of gelatine and allow it to remain until the gelatine congeals. The loaf then may serve to illustrate the three signs just named for a considerable period. Tympanitic resonance in a bread-loaf is illustrated by removing, in a portion of a loaf, all but the crust. The resonance is tympanitic over that portion, and vesicular over the remainder of the loaf. Vesiculo-tympanitic resonance is illustrated as follows: In a portion of a loaf remove a number of sections by passing through it a hollow cylinder of glass about half an inch in diameter. The distinctive characters of this sign are increased intensity, elevation of pitch, and the quality and combination of the vesicular and the tympanitic. These characters are obtained when several sections are removed in the way just stated, and they are brought into contrast with the imitation of the vesicular resonance by percussing over the portion of the loaf which remains intact.

Tympanitic resonance is illustrated by percussing india-rubber hollow balls and bags differing in size. Other things being equal, the resonance is higher in pitch the smaller the ball. The india-rubber bag enclosed within the leather case in the modern football, probably contains as much air as is generally contained within the chest in cases of pneumohydro or pneumopyo-thorax. The pitch of resonance on percussing such a bag inflated will be found to be higher than that of the resonance of the bread-loaf. This illustrates what I believe to be true—namely, that a purely tympanitic resonance in cases of disease is invariably higher in pitch than the normal resonance in the person examined.

The amphoric and the cracked metal resonance, which may be regarded as varieties of tympanitic resonance, are readily produced, the former by percussing indiarubber bags well inflated, and the latter by percussing hollow balls of small size with free openings. To obtain these varieties of tympanitic resonance, the bag or ball is to be held against the ear when the percussion is made.

RESPIRATORY SIGNS.

I know of no article by which may be illustrated the *normal vesicular murmur of respiration* as the normal vesicular resonance on percussion is illustrated by the loaf of bread. This murmur, however, may be produced outside of the body by using the human lungs, or those of the sheep or calf. Inserting the nozzle of a pair of bellows into the larynx or trachea, and imitating the acts of respiration, the distinctive characters of the normal respiratory murmur may be satisfactorily studied. The ear may be applied immediately to the lungs, covered with a few thicknesses of cloth, artificial respiration being produced by an assistant, or the stethoscope may be used. The binaural stethoscope is to be preferred. In using this instrument, here or on the living subject, care is to be taken that it is properly constructed. Many of these instruments are useless in consequence of defects in their construction. The bulbs at the aural extremities should be of a size admitting their easy introduction into the ear, but not allowing them to enter too far, and the curves at the extremities should bring the openings into the bulbs in the direction of the meatus. That the binaural stethoscope is not universally used is owing, in a great measure, to the want of knowledge or attention on the part of instrument makers as regards essential points in its construction. Lowness of pitch and a quality of sound which, like the vesicular quality in the normal resonance on percussion, is *sui generis*, are illustrated by artificial respiration in

lungs removed from the body. These are the distinctive characters of the normal vesicular murmur of respiration; and that they are produced by the movement of air in the air vesicles or alveoli, and not glottic sounds, as contended by Eichhorst and others, is proved by the fact that they are as fully reproduced by inserting the nozzle of the bellows into the trachea or a primary bronchus as into the larynx. My own theory respecting the mode of production of this peculiar quality is, that it is caused by the separation of the bronchioles, the walls of which are in contact and slightly adherent at the end of the expiratory act.

Bronchial respiration is illustrated by simply blowing into tubes of different sizes. Indiarubber tubes are to be used of sufficient length to reach from the mouth to the ear; in the latter situation being covered by the palm of the hand, in order to shut out extraneous noises. With an equal force of the current of air, the field of the sound is high in proportion as the tube is small. This sign may be studied by auscultating a lobe of lung solidified by pneumonia, after death, employing artificial respiration by means of the bellows, as already stated. Air enters readily into the bronchial tubes of a solidified lobe, and bronchial respiration may be produced by a current of air directed into a primary bronchus, as well as into the larynx or trachea. It is, however, probable that this sign in life is produced chiefly by the condition of the laryngo-tracheal respiration into the solidified lung, the medium of the conduction being chiefly air within the pulmonary bronchi. After death the sign is notably diminished over a solidified lobe if the primary bronchus be obstructed by a plug of cotton or wool.

The existence of a cavernous respiration with well-marked distinctive characters may be demonstrated out of the body. German authors, following Skoda, consider cavernous and bronchial respiration as identical in respect of their intrinsic characters, and the differential points were indicated in an essay published in 1852. The inspiratory sound in the cavernous respiration is low in pitch and hollow or blowing in quality. The expiratory sound has the same quality and is still lower in pitch. If the statement of these points of contrast with bronchial respiration be correct, the two signs need never be confounded with each other. That the statement is correct may be shown, in the first place, by a purely artificial production of cavernous respiration. Take an indiarubber balloon of the size of an orange, with thin walls and an opening at each end connected with an indiarubber tube. One of the tubes should be long enough to extend from the mouth to the ear. Applying the balloon to the ear, covering it with the hand, and with the mouth alternately inflating it and withdrawing the air from it by suction, the characters of the cavernous respiration are illustrated. The bellows may be used instead of the mouth, or the instrument known as Davidson's syringe. The cavernous respiration as thus produced may be contrasted with the bronchial respiration as illustrated by a current of air in the indiarubber tube employed in the foregoing experiment. The sign may, in the second place, be demonstrated by obtaining a specimen of phthisical lungs in which there is a cavity of considerable size near the periphery and not surrounded with solidified lung. By inflating the cavity and withdrawing the air from it by means of the bellows or Davidson's syringe, and applying the binaural stethoscope over the cavity, the cavernous respiration which existed during life may be reproduced.

All are familiar with the imitation of amphoric respiration by blowing over the mouth of a phial.

The musical intonation is also produced by blowing into an indiarubber bag of considerable size already inflated. I have found this sign well marked on inflating with the bellows a phthisical lung, and been led thereby to discover, by incision, a cavity in the centre of the lobe surrounded by solidified lung.

The sign which I have called the *broncho-vesicular respiration* embraces the abnormal respiratory sounds to which have been applied the names, *rude, harsh, rough*, and by German writers, following Skoda, *indeterminate respiratory murmurs*. The morbid physical conditions represented by this sign are all the varying degrees of solidification of lung falling short of a degree sufficient to give rise to a purely bronchial respiration. The varying characters of the sign denote the degree of solidification—that is, whether it be slight, moderate, or nearly sufficient to be represented by the bronchial respiration. The name *broncho-vesicular* expresses a combination of the characters belonging to the vesicular and the bronchial respiration. In the inspiratory sound the vesicular and the tubular qualities are combined in different proportions. Either the vesicular or the tubular quality may predominate. The pitch is low or high according to the predominance of the vesicular or the tubular quality. If the vesicular quality be predominant, the solidification is slight; if the tubular quality predominate, the solidification approximates more or less closely to that represented by the bronchial respiration. The expiratory sound is always prolonged and raised in pitch. The length of the expiratory sound, its intensity and the elevation of pitch, are proportionate to the predominance of the tubular quality in the inspiratory sound—or, in other words, to the degree of solidification.

The broncho-vesicular respiration cannot be artificially illustrated. It may, however, be studied by auscultating either human lungs removed from the body, or the lungs of the calf or sheep. Imitating respiration by means of the bellows, and applying the binaural stethoscope on the upper part of the lungs over the large bronchi, the characters of the sign are observed as contrasted with the vesicular murmur in other situations. The sign is, in fact, present in life over the large bronchi. It has been known as the normal bronchial respiration; but as the characters are not those of a purely bronchial respiration, a more correct term is the *normal broncho-vesicular respiration*.

ADVENTITIOUS SOUNDS OR RÂLES.

The important signs following in this division are the *moist bronchial* or *bubbling râles* (coarse, fine, and subcrepitant), the *dry bronchial râles* (sibilant and sonorous), the *crepitant râle*, *metallic tinkling*, and *pleural friction sounds*.

The moist bronchial or bubbling râles are artificially illustrated by indiarubber tubes differing in size. After forcing water, or any liquid, through the tubes by means of Davidson's syringe, there remains enough to give rise to these râles for some hours on passing a current of air either from the syringe or mouth through the tubes and holding them close to the ear. The bubbling sounds thus produced are coarse or fine according to the size of the tubes. The subcrepitant râles are produced within a tube of extremely small size. These râles may also be illustrated in lungs removed from the body, by introducing within the trachea water, or some other liquid, and imitating respiration by means of the bellows. If the quantity of liquid introduced be not large, it is quickly driven into the bronchial tubes of small size, and fine bubbling sounds over the subcrepitant râles are

produced. Coarser bubbling sounds are produced by the introduction of an additional quantity of liquid. If liquid be introduced, after death, into the bronchial tubes within a pulmonary lobe completely solidified, or in the second stage of pneumonia, the high pitch of the bubbling râles may be observed in contrast with the low pitch of râles produced within healthy lobes.

The dry bronchial râles may be produced by constricting abruptly the calibre of indiarubber tubes of small or moderate size, using for this purpose ligatures, or making compression with a pair of forceps or tweezers. It is, however, not easy to hit the proper amount of constriction. A current of air through the tubes may be produced by the bellows over the mouth, the tubes at the points of constriction being held close to the ear. The mechanism of the râles is in this way demonstrated, but I have not succeeded in illustrating them so as to approach to their abundance in cases of asthma. This, perhaps, might be done by getting together a number of tubes properly constricted at certain points.

The crepitant râle is well illustrated in various ways, with which every student of auscultation is familiar, such as rubbing a lock of hair close to the ear, throwing salt upon coals of fire, igniting a train of gunpowder, etc. The best illustration was afforded by an article made some ten or twelve years ago, of indiarubber, to be used as a sponge. Pressing this article close to the ear, and allowing it to expand, the imitation was as perfect as possible. This mode of illustration exemplified the mechanism—namely, the production of the dry crackling sounds by separation of bronchioles and alveoli in the act of expiration, which had become agglutinated by an adhesive exudation at the end of the expiratory act. An American writer, Dr. E. A. Corr, was the first to give this explanation of the mode of production of this râle in a communication published in the *American Journal of the Medical Sciences*, October, 1842. An article analogous to that just referred to is still in use by artists, and is known as the indiarubber sponge; but something is now combined with the indiarubber which renders it more useful as a sponge, but impairs its usefulness for the representation of the crepitant râle.

Metallic tinkling is very satisfactorily illustrated by means of the indiarubber bag of the foot-ball. Introduce into the bag half a pint or a pint of water; hold the bag so that the opening is dependent, and, by means of Davidson's syringe, introduce air so that bubbles will escape from the surface of the liquid. Holding the bag close to the ear, the escape of the bubbles gives rise to tinkling sounds. Invert the bag, and holding it quickly to the ear some tinkling sounds may be produced by drops of liquid from the upper part upon the surface of the liquid. The bag should be well inflated for the sounds to be produced. The sounds may be produced by shaking or percussing the bag when held close to the ear. But the best illustrations are produced by connecting the bag with an indiarubber tube of considerable length, and, after the passage of the liquid through the tube, enough remains to give rise to tinkling sounds for several hours on blowing through the tube and holding the bag close to the ear. In the last experiment it is not necessary that the bag contain any liquid. It should, however, be made tense by inflation. These different modes of producing illustrations of metallic tinkling represent corresponding physical conditions giving rise to the signs in connection with pneumothorax and large tuberculous excavations.

Pleural friction sounds are imitated by rubbing together the palms of the hands, and by placing

over the ear the palm and moving the finger over the dorsal surface of the hand.

VOCAL SIGNS.

The signs pertaining to the laryngeal or loud voice are *bronchophony*, *simple increase of vocal resonance*, *ægophony*, and *pectoriloquy*. None of these signs can be artificially illustrated, but, with perhaps one exception (*ægophony*), they can be readily produced in lungs removed from the body. Bearing in mind that the essential characters which distinguish bronchophony are elevation of pitch and nearness to the ear, intensity not being essential, this sign may be reproduced after death as follows: Remove the lungs from a subject dead with pneumonia, one lobe at least being solidified. Into the trachea insert the end of a tube nearly as large as the trachea, the other end of the tube being provided with a mouth-piece large enough to receive the lips. What is known as "Holden's resonator" is well adapted for these experiments. Now an assistant is to direct his voice into the speaking-tube, and the solidified lung is auscultated with the binaural stethoscope. The transmission of the voice gives rise to the bronchophonic modifications, the intensity being less than during life. Comparing the voice-sounds over the solidified lobe with those over a healthy lobe, the latter are found to have the distinctive characters of the normal vocal resonance—namely, diffusion and distance from the ear. The intensity of the voice-sound over the healthy lung is greater than over the solidified portion, showing that a healthy lung containing more or less air is a better conductor of sound than solidified lung. Experiments seem to me to prove conclusively that Laennec was in error in making the reverse of this statement. That the conduction of the voice-sounds into solidified lung is largely by the air contained in the bronchi, is shown by comparing the transmission when the trachea is unobstructed with that when it is plugged with cotton or wool. This comparison suffices to disprove the statement by Skoda and others, that the bronchi within a solidified lobe do not contain air. That air enters freely into the bronchi is shown by blowing with the mouth or bellows, into a tube inserted into either the trachea or the bronchus leading to the solidified lobe. Normal bronchophony may be illustrated, in healthy lungs, by comparing the voice-sounds over the large bronchi near the apex with those over the lower portion, an assistant speaking into a tube inserted into the trachea.

The characters which distinguish from bronchophony simply increased vocal resonance are to be clearly apprehended. In the latter sign the resonance is increased in intensity without the modifications essential to bronchophony—namely, elevation of pitch and nearness to the ear. Increased intensity without these modifications either denotes solidification of lung not sufficient in degree to give rise to bronchophony, or it denotes a cavity. The sign may be illustrated in the same way as bronchophony, over a lung partially solidified, or over a tuberculous cavity. A tuberculous cavity after death, as during life, may give intensely increased vocal resonance without the bronchophonic characters; this is when the cavity is large, near the surface, and not surrounded by solidified lung. Increased vocal resonance, not bronchophonic, within a circumscribed area is often a valuable cavernous sign.

Ægophony has one of the essential characters of bronchophony—namely, elevation of pitch. It lacks the other essential character—namely, nearness to the ear. Other distinctive characters are tremulousness, bleating, and the nasal intonation. The high pitch and distance from the ear are ob-

tained by placing beneath the stethoscope, in a situation in which bronchophony is well marked, a bag of liquid; but the additional characters are not in this way produced. I have no practical knowledge of any mode in which complete ægophony may be produced out of the body. The conditions in life may be imitated by placing within an india-rubber bag lungs with a solidified lobe, introducing into the bag a certain quantity of liquid, and auscultating, while an assistant speaks into a tube inserted into the trachea. This experiment I have not tried. The interest belonging to this sign relates chiefly to the mechanism of its production; for, with the other signs denoting pleuritic effusion, together with the exploratory needle, the sign cannot be said to have much practical importance.

Pectoriloquy is often confounded with bronchophony. All confusion is avoided by defining pectoriloquy to be the transmission of *speech*—that is, not merely the voice but articulated words. As thus defined, pectoriloquy may perhaps be illustrated over a solidified lung by speaking into a tube inserted into the trachea. I have not succeeded very satisfactorily in two instances in which I have tried to illustrate it in this way; but the instances have been few. It would be of interest to ascertain whether the sign may be illustrated as heard over a solidified lung and over a cavity not surrounded with solidified lung. The object would be to verify out of the body an important practical distinction pertaining to this sign during life. The distinction is one which I believe I was the first to indicate. It is this: If pectoriloquy be accompanied by the distinctive characters of bronchophony the conduction of the speech is through the solidified lung; but if the characters of bronchophony are wanting the pectoriloquy is a cavernous sign. By means of this distinction it is practicable, in cases of disease, to determine whether the sign denotes solidified lung or a cavity.

WHISPERING SIGNS.

A series of signs produced by the whispered voice was arranged by me, and the different signs (pectoriloquy excepted) named in 1856. The whispered sounds of health were embraced under the name *normal bronchial whisper*. The morbid signs, correlative to those produced by the loud voice, were called *whispering bronchophony*, *increased bronchial whisper*, *cavernous whisper*, *whispering pectoriloquy* and *amphoric whisper*. It is unnecessary to describe the differential characters of these different signs, inasmuch as they are those which belong (following the same order of enumeration) to the expiratory sounds in bronchial respiration, broncho vesicular respiration, cavernous respiration and amphoric respiration. Pectoriloquy is, of course, excepted. The experience of many years has confirmed the opinion that these signs are often serviceable in the practice of auscultation; albeit their analogues are to be found in the respiratory signs just named. The distinctive characters are brought out more fully and distinctly by the whispered voice than by the expiratory acts in respiration. The whispering signs may be fairly represented by means of diseased lungs removed from the body, an assistant speaking in a whisper into the trachea, and the stethoscope placed over portions of lung in different degrees of solidification, over cavities with their walls near the surface, and over cavities surrounded by solidified lung. Let me add, that the characters distinctive of whispering pectoriloquy as a sign, on the one hand, of solidified lung, and, on the other hand, of a cavity, are not less marked than those of pectoriloquy produced by the loud voice. If whis-

pered words transmitted through the chest are accompanied by a sound high in pitch and tubular in quality (whispering bronchophony), the conduction is through solidified lung; but if the word sound be low in pitch and non-tubular (cavernous whisper), the conduction is through a cavity.

I have given, gentlemen, a succinct account of the production, out of the body, of pulmonary signs obtained by auscultation and percussion, for reasons which were stated at the beginning of the lecture. I do not profess to be an adept in devising methods for the illustrations of these signs. I doubt not, that many of you, by the exercise of your ingenuity, will be able to do better than I have done. Efforts in this direction, as it seems to me, will be likely to be more useful than attempts to elucidate the physical signs by resorting to abstruse principles of physics. It would be easy to show that the latter method of investigation has led to important practical errors. The physical elements involved in certain of the signs are too varied and obscure to be embraced in mathematical calculations. This difficulty does not apply to experiments having for their object the imitation of the physical conditions which the signs represent, and to those made upon the lungs, healthy and diseased, after death. Teachers of auscultation and percussion will, I am sure, find much advantage in producing the signs out of the body in the class room, in conjunction with clinical illustrations, and I hope hereafter to be able to do more in this way than I have done during the present session.

Clinical Remarks

ON

ABDOMINAL SANGUINEOUS CYSTS.

By J. S. BRISTOWE, M.D., F.R.S.,

Senior Physician to St. Thomas's Hospital.

ONE autumn, seventeen or eighteen years ago, I went to Hastings with my wife and family, and on the platform of the station met a young lady with whom and whose family I was acquainted. She looked miserable, and told me that they had all been there several weeks on account of the illness of one of her brothers, who was, in fact, then dying. I was surprised, for I had heard nothing whatever of the matter, and had seen him only a few months before, apparently in perfect health. A little later in the day she called at my lodgings to request me to see him in consultation with his medical attendants, Mr. Barnard and Dr. Adey; and in the evening we met. The patient was a young man, twenty-seven or twenty-eight years of age, of loose habits, but who had (so far as I know) enjoyed very good health. His present illness was of a few months' duration only. He had been ailing for a month or two at home with symptoms referable to the abdomen, but which his own medical man, failing to understand or to benefit, sent him to the seaside to get rid of. He gradually became worse, however; and before long an abdominal tumour of large size was discovered. This rapidly increased in volume, and concurrently with its enlargement the patient emaciated and got weak; he had suffered also, more especially latterly, from intense abdominal pain, coming on in frequent paroxysms. I found him in bed, lying on his back, with his head and shoulders raised. He was pallid and sallow looking, emaciated to the last degree, but with an enormously distended abdomen. His general aspect, in fact, was precisely that of a woman in the last stage of untreated ovarian dropsy, or of a

child sinking from the effects of a malignant tumour of the kidney. He had no appetite, and indeed vomited (as he had done for some little time) everything that he took. He was in much pain during the whole time of my interview with him, and now and then appeared to be in extreme agony. It was supposed that his end was near, and I confess that I shared that view. On careful examination, I found a large ovoid, but somewhat irregular tumour occupying mainly the left side of the abdomen; it extended from the ribs above to the pubes below, and from the left loin to a couple of inches or so to the right of the umbilicus. The bowels were pushed to the right, there was no fluid apparently in the peritoneal cavity, and, with the exception of the large tumour, no evidence of abdominal disease. I may further state, at once, that the thoracic viscera were all healthy, that none of the superficial glands were enlarged, and that the excretory functions and products were normal. The tumour, when first discovered, was assumed to be malignant, and to have originated in the liver. Its position now, however, did not in the least suggest an hepatic origin. It seemed rather to be connected with the spleen, or kidney, or peritoneum in the neighborhood of these organs. It was fixed; it presented no notched edge, nor indeed any edge at all; and so far as could be made out the large intestine did not cross its surface. Which of the latter alternative views of its origin was the correct one was undeterminable by ordinary physical examination. It was, however, cystic, and it was decided to tap it. The next morning a large-sized trocar and cannula were introduced, and at least a gallon and a half of opaque, turbid, dark, reddish-brown fluid were removed, with the result that the cyst was nearly emptied, and not much evidence was left of its presence in the abdomen. The fluid was simply altered uncoagulated blood, and the only microscopic elements detected in it were ordinary red and white corpuscles.

I left Hastings after that for a fortnight, and when I returned I found our patient able to sit up and enjoy some hours daily on the beach, gaining flesh rapidly, free from pain, with a good appetite, and sleeping well. Indeed, he was advanced in convalescence; but the cyst was refilling. I saw nothing more of him at this time; but learnt that at the end of two months from his tapping the tumour had become almost as large as ever, and paracentesis had again to be resorted to, and that the fluid removed was of the same quality and almost as abundant as that removed on the first occasion. He had, however, retained his renovated health to a large extent. The fluid never reaccumulated after the second tapping, and after the lapse of two or three more months he returned home perfectly well and able to resume his occupation.

I may as well give the subsequent history of this case at once, with its episodes, for they are interesting, though they have little relation to the main object of this lecture.

Shortly after his recovery from the above illness the patient married a young lady to whom he had been for some time engaged, and who had nursed him, and took up his residence in one of the suburbs of London. I did not see him again for three or four years, when I was requested to attend him in consultation. I found him living in very good style, but he had been drinking rather heavily, and was suffering in consequence from an attack of delirium tremens. When I entered his bedroom he was laughing heartily, and it was some time before I could get him to explain the cause of his mirth. He told me at length that just before I arrived he fancied he had seen,

through his window, a number of naked men running one after another across some fields, and leaping over a ditch that divided them, while a person concealed in the ditch, and armed with a razor, lopped off each one's privates as he jumped. Not a trace of his old abdominal tumour could be detected. It is a pity, however, that he had not been treated at this time as the phantom jumpers had been treated by their phantom enemy, for shortly afterwards he imparted syphilis to his wife, from the effects of which she ultimately died. The next time I saw him was some seven or eight years ago, when I was requested to admit him under my care into St. Thomas's Hospital. He had for some years taken to drinking; he had been turned out of the business in which he was a partner; he had sunk into the lowest depths of degradation; and for a year had been living with a prostitute and on the proceeds of her traffic. He was filthy and squalid and worthless, and he was suffering mainly from filth-sores about his body and enlarged lymphatic glands resulting therefrom. Again I examined his abdomen most carefully, and again could discover no sign whatever that he had at any time suffered from abdominal disease. For the third time he recovered. I have seen him once since, in rags and begging, in Cornhill, but where he is and what he is doing now I have not cared to inquire. I hope I may have done some good in my time. I certainly looked back for a few years with special pleasure to my share in the successful treatment of this case; I look back to it now with regret and almost with remorse.

What was the nature of this man's tumour? Was it a portion of the peritoneal cavity, cut off from the rest by adhesions, and in connection with a rupture of the spleen or some other viscus? I have seen such a cyst, on the right side of the body, due to rupture of the liver, and containing altered blood, the patient surviving many weeks. There was no history, however, of injury in this case, and, moreover, the symptoms were slowly developed. Was it a simple cyst arising in the peritoneum, spleen, or kidney, the secretion into which had assumed a hæmorrhagic character? If this were its nature it had most probably, I think, originated in the spleen; but I have never met with any such cyst even in this organ. Was it an hydatid? I should think not, for many reasons, and amongst others because even after the most careful examination by several competent observers no trace of hydatid membranes, of microscopic cysts, of echinococci, or of hooklets was discovered. Was it a case of rapidly developed and gigantic hydro-nephrosis, or (as I presume it should be called) hæmato-nephrosis? I think it was either a simple cyst of the spleen or a distended kidney, and on the whole I lean to the latter opinion. I confess, however, that its nature has ever been a mystery to me, and I have always hoped that sooner or later some elucidative case would present itself before me.

The case which most resembled it first came under my notice early in 1879, and for a time seemed so close a copy of it in its phenomena that I looked forward hopefully for an equally happy result. But, alas! I was doomed to disappointment; for my poor friend, as I like to think him (for he was a man of character and culture, and grateful in the highest degree to all about him for their efforts in his behalf), after remaining intermittently under my care for several years, died of his malady last summer. He was a newspaper reporter and writer, of dark complexion and delicate physique, who towards the end of the year 1878 first began to complain of the symptoms of the malady for which he placed himself under my care in St. Thomas's Hospital on Feb-

ruary 20th, 1879. He was then thirty-five years of age.

On admission it was found that he had a large belly (the veins in the walls of which were dilated), and that the enlargement was due to the presence of a tumour which occupied its lower part. This was rounded and symmetrical in shape, extending from an inch or two above the navel to the pubes, and from one anterior superior iliac spine to the other. There was absolute dulness in all this area and distinct fluctuation. It was neither tender nor painful, nor did it present the hydatid thrill. The abdomen was in all other respects healthy. The thoracic organs also were healthy. He had a good appetite, but could take very little food. His bowels were constipated, and opened only every three or four days. The urine was abundant, and had a specific gravity of 1014, and contained a trace of albumen. He slept badly, and complained of a dull aching pain about the anus, extending thence up the rectum, and also of pain about the umbilicus. The girth of the abdomen at this time was about thirty-three inches. The tumour, from its situation, might well have been the distended bladder; but it was broader than a bladder might be expected to be, and extended higher. A catheter was passed, however, and the vesical contents were removed, but without any effect on the tumour. Then an aspirator was introduced into the cyst, and a few ounces of fluid were withdrawn. This was reddish-brown, grumous, alkaline, with a specific gravity of 1024, became consolidated by boiling, contained abundant chlorides, and under the microscope showed numerous blood-corpuscles, but no other morphological elements. The resemblance of this cyst to that in the case first narrated naturally struck me; and the question I had formerly failed to answer again rose to my lips, What could be its nature? In this instance, however, it was clear that we had to do neither with a spleen nor with a kidney; neither was there any more evidence in this case than in that that the cyst contained hydatids. There was evidently, however, some ground for hoping that they might be, and, indeed, for thinking that they were, identical in their nature. After he had been in the hospital three weeks, his girth at the umbilicus had increased to thirty-four inches; and it was determined to tap the cyst. This was done with the aspirator, and 128 ounces of fluid, exactly like that obtained by the exploratory puncture, were removed. The patient was relieved from many of his discomforts, and no ill effects of any kind followed. On examination of the abdomen a day or two afterwards, its girth was twenty-nine inches and a half, and no trace of the tumour could be felt through the abdominal walls. There was a little tenderness, however, in the left iliac fossa. About a week later it was noted that dulness on percussion extended upwards two inches from the symphysis pubis; and from this time, with the exception that there was difficulty as regards the bowels, the patient improved in health and strength. The cyst, however, was slowly enlarging. On May 20th his girth was thirty-two inches, and it was thought advisable to tap him a second time. Eighty-six ounces of fluid were removed on this occasion; it was redder than, but in other respects exactly of the same character as, that removed previously. He left the hospital, much benefited, on June 8th.

He was readmitted on July 3rd, and, as he was then suffering much as he had done when he first came under treatment, it was decided to tap him at once, although the tumour did not reach the umbilicus by two inches. Seventy-four ounces of fluid, exactly like the last, were removed by the aspirator next day. A week later he got a slight at-

tack of acute rheumatism, from which he recovered in the course of a few days. And again he left the hospital, much improved, on July 19th.

On Feb. 27th, 1880, he for the third time became an inmate of St. Thomas's. He had been suffering from abdominal pain, difficulty of breathing, some cough, sleeplessness, constipation, and more or less difficulty in micturition. His tumour was larger than it had been, and extended to two inches above the navel in the mesial line; its shape was unaltered, and it still fluctuated; but its walls were manifestly thicker, and there was an oval solid tumour, about an inch and a half in length on the right side, between it and the abdominal wall. This was freely movable and somewhat tender. The girth of the abdomen was thirty-three inches and three-quarters. On March 4th 167 ounces of fluid, exactly like that formerly yielded, were removed by tapping. The girth of the abdomen after the operation was twenty-nine inches and a half, but the tumour could still be recognized as a more or less solid mass, occupying the region above the pubes. There was a gradual but slow increase in the size of the tumour after the operation, and at length, as the patient's health was deteriorating, as my original hopes were as to the cure of the tumour seemed doomed to disappointment, and as also it was evidently becoming more solid, I consulted Mr. Sydney Jones as to the feasibility of its removal by abdominal section. On May 13th, the patient being kept under the influence of anæsthetics, Mr. Jones inserted his hand into the rectum, and made a combined rectal and vesical examination, with the result of discovering that the tumour dipped deeply into the pelvis, between the rectum and bladder, displacing the bladder to one side, he concluded that it was inexpedient to perform any such operation as had been contemplated. On June 4th the cyst was tapped for the fifth last time, when only seventy-eight ounces of fluid were removed. Subsequently to this, the tumour slowly increased in size, and altered in shape, becoming somewhat lobulated and more solid, as my note says, "fleshy;" then it appeared stationary for a time; and, finally, it was thought to undergo distinct diminution, which continued up to the time at which he left the hospital Nov. 27th. At that date the highest point of the tumour reached the level of the umbilicus; and a separate, movable lump had either receded so far out of reach of the finger, or had become incorporated into the larger mass. During this stay in the hospital his health varied a great deal, but on the whole he got thinner and weaker. His bowels were usually constipated, and he had a continuous discomfort after the rectal examination there was frequently some difficulty in passing urine, and this fluid varied in specific gravity, quantity and in quality; it often contained more or less albumen, and occasionally a little blood and traces of pus. Latterly, too, it was abundant and of low specific gravity. His appetite poor, he complained of pain and tenderness in the abdomen, his pulse was feeble, and his temperature for the most part was normal or subnormal. He had during this time a little temporary oedema of the legs, and on one occasion there was a break of petechial spots over the abdomen and lower extremities. He lost nearly a stone in weight during the nine months.

It was not until May 19th, 1882, or after an interval of eighteen months, that he again came under admission into the hospital. He had been coming up almost daily to have morphia injections, and reported himself from time to time to the doctor, and had been seen by myself occasionally in the street or in the hospital. He was very weak

ing all this time, and seemed if possible to get thinner, but the abdomen remained considerably smaller than it was when it used to need tapping, and he thought it was still diminishing. For the last month, however, he had been distinctly losing ground, and especially had been suffering from cough and expectoration, with spasmodic difficulty of breathing, and frequent vomiting.

On admission the abdomen was large and prominent, and the superficial veins in its lower part were dilated; the tumour, which was certainly smaller than when last examined, was lobulated but rounded in outline, slightly movable, somewhat soft to handle, but free from all sense of fluctuation. It appeared to be a softish solid mass, and was very tender. The chest was fairly resonant, but over the upper part of the right side there was dullness with loud creaking, sonorous rhonchus and harsh expiration; and over the middle third behind crepitation. He had a frequent cough and expectorated much nummulated muco-purulent fluid. The tongue was dry, red, and glazed; he was thirsty and had no appetite; the bowels were confined. He passed a great deal of water, which was turbid, acid, contained one-sixth of albumen, and some pus cells, but no casts. His pulse was quick and feeble, and his temperature ranged from 98.2° to a little over 100°. He complained much of pain across the lower half of the abdomen and in the back. His remaining clinical history is little more than a simple record of the incidents of death from asthenia. He gradually got weaker, his pulse feebler and falling from about 120 to 96, his temperature becoming subnormal. His cough and expectoration continued, and the latter became fetid. Inflammation of both eyes supervened, resulting in ulceration of the left cornea. He became also forgetful, and wandered slightly in his mind. Abdominal pain continued until his death, which took place on June 24th, 1882. During all this period his treatment consisted mainly in the subcutaneous exhibition of morphia, which had been largely employed throughout his illness, and the administration of food and stimulants.

A curious circumstance occurred a day or two before his death which it may be worth while to record. I was discussing the case with my class, and was especially considering the fact that the original thin-walled cyst had become almost completely solid; and I proceeded to examine the patient, when to my surprise his tumour appeared thin-walled and fluctuated distinctly in almost its whole extent. It turned out that the patient in his half unconsciousness had retention of urine, and the distended bladder in the shape of a tea-cake had intruded itself temporarily between the tumour and the abdominal wall.

Autopsy.—The body was emaciated to the last degree. Chest: The left pleura contained a few ounces of blood-stained fluid, and the left lung was large, oedematous, and congested. The right lung was adherent over the upper lobe, but the lower part of the pleural cavity was occupied by purulent fluid. Near the anterior border of the lower lobe was an ulcerated opening the size of a shilling, by which the empyema communicated with the lung tissue. In the upper lobe was a large irregular cavity of new formation; and in the lower lobe was a smaller cavity which had opened into the pleura. No tubercles or other kind of adventitious growth was found. The remaining lung tissue was collapsed. Heart and pericardium healthy. Abdomen: A large and irregularly rounded tumour occupied the lower and anterior part of the abdominal cavity, extending from above the umbilicus into the pelvis, and displacing the intestines upwards and backwards. The distended bladder lay between the lower part of its

anterior surface and the abdominal parietes. Its exact seat of origin was not determined; but its lower part extended to the bottom of the recto-vesical pouch, and it was intimately connected with the soft tissues in front of the sacrum and with the parietal peritoneum of the lower part of the sides and back of the pelvis. The tumour was a thick-walled cyst. The walls varied from about half an inch to an inch and a half in thickness, and consisted for the most part of a moderately firm, whitish, semi-translucent material. The inner surface was lined with an opaque buff-colored mortary layer, which infiltrated the adjoining solid wall to a depth of a line or so; and here and there isolated patches having the same appearance and small hemorrhages studded the substance of the walls. The central cavity was now comparatively small, and flattened from before backwards, but contained many ounces (probably a pint and a half) of turbid, opaque, light-brown fluid, looking much like a solution of the solid matter lining the cyst. The tumour weighed 7 lb., and was a round-celled sarcoma. A few small outlying solid growths of the same texture as the primary tumour were found in close proximity with its posterior surface. No secondary growths were discovered either in the neighboring glands or elsewhere. The bladder was distended but healthy. The kidneys were both moderately hydronephrotic. The spleen was large and firm. All the other abdominal organs were sound. Brain healthy.

It seems to me now, looking back on the case of my poor friend, that it was in the main a very simple one; and that only a fatal issue could have been anticipated from the beginning, had one recognized the pathological character of the growth within which the cyst, so frequently tapped, had become developed. No doubt the growth from its origin was, as it proved to be ultimately, a round-celled sarcoma; and that (although the exact organ or structure in which it arose was not determined) it sprang from the cavity of the pelvis. It is clear, too, from the progress of the case, that in the beginning the vascular sarcoma broke down in its interior into a sanguineous cyst which rapidly increased in size, with probable attenuation of its walls, until it attained the dimensions presented by it on the occasion of the first tapping; and that from this time onwards there was progressive invasion of its walls by sarcomatous growth, and progressive thickening, which gradually rendered the tumour more and more solid to the touch, which, in association with the degenerative changes in the inner surface of the cyst, checked and finally arrested the enlargement due to simple fluid-accumulation, and explained equally the diminishing need for tapping, and the reduction, at any rate for a time, of the tumour in bulk. The same process had, in fact, been going on here as one occasionally witnesses in cysto-sarcomatous tumours of the ovary, and in cystic ovarian tumours which become invaded by sarcomatous growth. The persistent constipation and frequent difficulty of micturition were obviously due to the pressure of the tumour on the pelvic organs; and the variable, and for the most part abnormal, condition of the urine was doubtless dependent on the hydronephrosis, which itself had resulted from partial obstruction of the ureters. The pulmonary abscesses and empyema were apparently unconnected with either tubercle or sarcoma, and probably the result of a low form of pneumonia determined, like the affection of the patient's eyes, by his extreme debility and imperfect circulation.

In conclusion, do these cases throw that clear light on one another that I had expected? or do they even throw any light at all on one another?

I am bound to acknowledge that I think not. They both furnish examples of rapidly developing cysts with sanguineous contents. But there all real resemblance between them ceases. They illustrate the facts, however, that cysts of different origin and of different structure may so far resemble one another in the conditions of their lining membrane as to secrete morphologically and chemically identical fluid contents; and that morbid developments of the most diverse kinds may yet have common characteristics. At any rate it will be admitted, I think, that the cases are far more instructive when considered together than either of them would be taken alone.

Original Papers.

NOTES OF TWO UNCOMMON CASES OF ABSCESS OF BONE.

By WILLIAM S. SAVORY, F.R.S.,

Surgeon to St. Bartholomew's Hospital.

EVER since Brodie directed attention to the subject, surgeons have learnt to recognize the characters of abscess of bone. We are now familiar with its more common forms, but varieties of this affection occasionally occur which have been hardly noticed. In certain instances not only is pus found in a well-defined cavity, but also a sequestrum lying loose in the fluid. Such a state of things, may be understood without difficulty. The inflammation here has produced not only suppuration, but the death, also, of a considerable fragment of bone. But the following two cases are examples, I believe, of a still more rare condition.

A man, thirty years of age, not very robust, was admitted into the hospital in November last, complaining of much pain in the upper part of the left tibia, from which he had suffered for the previous six weeks. He described the pain as deep seated and dull, but variable. There was general enlargement of a portion of the bone, most marked at the junction of the upper and middle third. At this part the limb measured an inch and a half more than the opposite one. Here, over the tibia, and adherent to it, was a longitudinal scar, some three inches long, on the surface of which was a small aperture, and from this two or three drops of pus occasionally exuded. He gave the following history. Sixteen years ago he was struck on the left shin by a cricket ball. After a while the bone became painful and the leg began to swell, but for some years he did not suffer much. Seven years after the accident all the symptoms became aggravated and pointed clearly to an abscess in the tibia. Nine years ago I trephined the bone and exposed an abscess about three inches in length. The wound gradually closed, and for five years after the operation the man was free from all trouble, but about four years ago the bone again became painful, and then some pus escaped from the site of the old wound. The chief features of the case since that time he very clearly described, and his description was confirmed by what was observed in the hospital. After a period of freedom from suffering he would be troubled for some days with severe pain in the part, which gradually increased up to a certain pitch, and then almost suddenly ceased. This cessation would be marked by the formation of a small abscess in the scar, which would burst, discharge, heal, and leave him free from pain for some weeks, when it would be-

gin again, and lead up to an abscess as before. When the scar was reflected from the surface of the tibia, a very small indentation was observed in the centre of the prominent bone, and here, by the aid of a fine probe, a minute aperture was discovered, only just large enough to admit it, which led, at some depth, to a cavity in the interior. This was opened and found full of pus, holding about two drachms. The state of things was then clear enough. It was a case of abscess in the tibia, but with the striking fact that it communicated with the exterior by a fine canal, and this explained the peculiarity of the symptoms. They were not of the urgent and characteristic kind usual in cases of abscess of bone, for when the cavity became filled, tension was relieved by the escape of pus from time to time to the surface. The question how such a condition had been brought about is more difficult to answer. Was this fistulous tract the remains of a process by which this abscess had, during its course, made its way to the surface, as in the instances mentioned by Mr. Carr Jackson? In the history of this case there was no evidence of this. Had it been the result of incomplete repair after the first operation? It is hard to understand this with a period of five years' absolute freedom from all trouble. But if not, how came such a delicate fistulous passage to form? My view is that repair after the first operation could never have been thorough and complete.

A delicate girl, eighteen years of age, was admitted into the hospital on the 15th of last January, with the following history:—Her health had been good until seven years ago, when she struck the right shin. This was followed by inflammation of the knee-joint, and mischief in the upper part of the tibia. Abscesses followed, and at length several pieces of dead bone were removed from the shaft. She recovered from this. The wound healed and remained sound until a fortnight before admission, when dull, aching pain began in the site of the old injury, and increased until the day before she came to the hospital, when matter was discharged with much relief. In front of the upper part of the right tibia was an irregular scar, about two inches long. Near the centre of this was a small sinus discharging a little thin pus. At this part there was a general enlargement of the bone, ill defined, with a smooth surface, but indented under the scar, which was adherent to the periosteum. There was great tenderness on pressure over the scar. There were other scars of previous abscesses in the limb, one over the inner condyle of the femur, and another just above the internal malleolus. The scar was dissected back, then on the surface of the bone a very minute orifice was seen, too small to admit a probe, through which a drop of pus exuded. With a drill this was enlarged, and the cavity of an abscess was exposed in the shaft of the bone. It was regularly oval, with perfectly smooth walls, about an inch in length, filled with pus. Again, in this case how can the formation of the slender fistulous canal be explained? Could it have remained since the first operation, or had it been produced at some subsequent period? It seems to me that neither view can be accepted without difficulty. We are certainly not familiar with these extremely minute fistulous tracts in the substance of bone. But the clinical features of these cases are very remarkable. With many of the usual signs of abscess of bone, one—perhaps the chief—intense and long-continued pain, admitting of no relief, and rising at times into great agony, was wanting. And the explanation of its absence is easy. The pain of such an abscess is due to its tension, and

here, as the pressure from the accumulation of pus increased, the fluid found vent to the surface with corresponding relief.

ON A CASE OF OBLITERATION OF SUPERIOR VENA CAVA.¹

By GEORGE WILKINS, M.D., M.R.C.S. Eng.,

Professor of Physiology and Lecturer on Histology, University of Bishop's College; Physician to Montreal General Hospital.

(Reported by Dr. DUNCAN, Resident Assistant-Physician.)

CHARLES R—, aged thirty-four, third officer of an ocean steamship, entered hospital on the 27th of June, complaining of great shortness of breath and a feeling of fullness in the head. He said that twelve months previously, when lifting a heavy weight, he felt something give way in his chest; this was immediately followed by severe dyspnoea and weakness, and he was obliged to give up work for a time. He soon became better, but for six months after this he had occasional attacks of dyspnoea, very severe at times. He also had pain in the region of the heart, extending to the left shoulder. The severe symptoms then abated till about four weeks ago, when he became much worse. When ascending the gangway of the ship he suddenly felt "as if he would smother," and coughed up a small quantity of blood. He soon became easier, but still had considerable dyspnoea on exertion. Four days ago his breath became very short; he felt a fullness in the head and had slight pain extending down each side of the neck. He said he never was a hard drinker, but he had the appearance of a man who had lived well. No history of syphilis. The chest and other parts of the body presented spots of enlarged capillaries. Heart sounds perfectly clear. No perceptible impulse at the apex. There were swelling and tenderness on each side of the neck, just over the great veins; no enlargement of glands; no pulsation in supra-sternal notch. Laryngoscopic examination gave negative results. Breathing appeared rough at apex of both lungs; percussion note was clear over both lungs, and breath sounds heard distinctly. No increase in liver or spleen dulness. When sitting up could breathe fairly well, but the slightest exertion in lying down caused urgent dyspnoea. He had had a slight laryngeal cough, though not of a clanging character. Urine normal in amount, and containing no albumen and no casts. Temperature normal; pulse 84. Ordered a purgative and nitrite of amyl (three minims) inhalation when the dyspnoea became severe.

June 30th: Passed a very bad night; great difficulty in breathing; eyelids oedematous; considerable lividity of the right ear; no alteration in physical signs. Ordered thirty grains of iodide of potassium three times a day.

July 4th: Complained of great tenderness on the right side of the neck, behind the posterior border of the sterno-cleido-mastoid muscle; no improvement in the breathing. Ordered the painful parts of the neck to be smeared with equal parts of glycerine and extract of belladonna; also a saline purge.—11th: The tenderness in the neck had disappeared, but the dyspnoea was very great; face oedematous and ears livid; a little oedema of the scrotum.

Aug. 4th: Percussion note over the heart and lungs, which previously had been found quite normal, was dull below the nipple on the left side; directly outside the nipple the breathing was

blowing; behind on the left side the percussion note was dull up to an angle of the scapula, with weak breathing over the dull area; an occasional moist râle was heard behind; breathing not altered over the right lung. Increased lividity of the face; eyes quite closed from the swollen condition of the lids; no oedema of scrotum.—8th: Patient felt easier; was able to lie down and sleep; breathed comfortably when he kept quiet.—13th: Dyspnoea very urgent; face much swollen; ears livid; some oedema about the arms and chest; percussion note dull on left side below nipple and in lower axillary region. An aspiratory needle was introduced into the axillary line at the eighth rib, and four ounces of clear fluid removed, with relief to breathing for some hours.—23rd: Considerable oedema and lividity of face; on left side in front the percussion note was dull from the second rib to the base of the lung, the dullness extending to the posterior axillary line and also across the sternum two inches beyond its right edge; behind the note was clear. Good vesicular breathing was heard over the entire back and above the second rib in front; below this point no breath sounds were heard, nor in the axillary region. Tactile fremitus was diminished. The heart's impulse was not seen; but the apex beats were in normal position as fixed by stethoscope; sounds clear, but distant. The left side of the chest was aspirated with a fine needle in the fifth interspace directly outside the nipple line, but no fluid was obtained; the same interspace in the line of the axilla was tried, and seventy-six ounces of clear yellow fluid were removed. After the tapping the percussion note became clear down to the seventh rib in front and in the axillary line, and was clear behind. Breath sounds more distinct, and a grating friction sound was heard in the previous dull area. The breathing became easier for a few hours, but towards night the patient began to cough and said he felt a gurgling in the throat; he did not lie down the whole night, and the next day the lividity and dyspnoea were as bad as before.—28th: Again aspirated, and forty-four ounces of fluid were removed from the left side.

Sept. 1st: The chest again filled with fluid; the left pleural cavity aspirated, and fifty ounces of fluid were removed. This state of affairs continued for over a month, the chest filling with fluid and causing urgent dyspnoea. This was relieved every second or third day by tapping with an aspirator, usually in the axillary line. Occasionally the right side of the chest was aspirated, but did not give the same relief as the left side. The amount of fluid removed at each aspiration varied from twenty to seventy ounces. The fluid never showed any tendency to become purulent, but was a little bloody on one or two occasions. The urine was repeatedly examined during the course of the disease, and was never found to contain albumen. He never had any oedema of the legs, and, during the last six weeks, no oedema of the scrotum. At no time was there any ascites. The face was often excessively swollen and very livid, and there was also pitting on pressure on the sternum.

Oct. 9th: The distress in breathing was so great that a Southey's cannula was introduced into the left pleural cavity through the seventh interspace in the axillary line; a piece of fine rubber tubing, previously filled with carbolic acid lotion, was attached to it by one end, the other end being immersed in a vessel containing lotion. In this way the fluid was drained away, and the patient felt some relief; but on the following day the cannula came out. It was again introduced on the 11th, but after a short time the tubing appeared plugged with coagulum, and the fluid ceased to flow away. Previous to this the pulse had never been over 104,

¹ A paper read before the Medico-Chirurgical Society of Montreal, Dec. 8th, 1882.

and the temperature had been normal. On the evening of the 11th he complained of pain in the left side, and felt feverish. On the 12th a hot poultice was applied to the side which was still painful. The tongue became furred, the pulse rapid (116); temperature 102° F.; respiration 38. The distress in breathing was extreme. Both the pleural cavities were now aspirated; from the left side twenty ounces of bloody fluid were removed, and from the right forty ounces of clear limpid serum. This relieved the dyspnoea, and caused the lividity to disappear for a short time. On the 13th the patient became much worse: respiration 50; pulse 120; temperature 103° F. Towards night he became much weaker, dyspnoea severe, and finally drowsiness supervened with cyanosis. At 11 p.m. he died. The whole amount of fluid removed from the chest by aspiration was 862 ounces, the greater portion coming from the left side.

Autopsy by Dr. OSLER.—The body was that of a large stout man. The face and upper extremities were swollen; the face was very livid. On opening the thorax a large quantity of fluid was found in the right pleura; in the left there was not so much, and the membrane was covered with recent lymph. In the anterior mediastinum, between the aorta and the right lung, there was a thickening of the tissues, and a firm, cord-like structure extending towards the root of the neck. In the right auricle were blood and clots, and there was considerable distension of the chamber. The superior vena cava was found to be obliterated. There was a funnel-shaped projection of the auricle towards the region of the obliterated vessel. There was a valvular opening between the auricles. On section of the vein it was found converted into a firm fibrous cord, the ultimate result of a thrombus in the vessel. Organized thrombi extended into the innominate and internal jugulars. There was nothing special in the other chambers. The left ventricle was large, and the walls thick. The right branch of the pulmonary artery was a little compressed beneath the fibrous cord. The left lung was much compressed, and sodden at the base, and contained much blood. The pleura was covered with fibrinous exudation. The right lung was also compressed. The azygos veins were much enlarged. There was nothing special in the abdominal organs. A large number of sections from various parts of the thrombosed vessels were made by means of the freezing microtome, for the purpose of microscopical examination. The most interesting were those taken from the vena cava superior, especially those from its cardiac extremity. On examining one of these with the naked eye by means of transmitted light it showed a deep staining, three millimetres wide, which involved not quite the entire circumference of the vessel, whilst the lumen of the vessel itself, which could be distinctly seen filled with clot, was considerably reduced in size (six millimetres). On examining beneath the microscope this staining was seen to be composed of dense cicatrized tissue, involving the coats of the vein and extending quite up to the intima. This cicatrized condition extended upwards along the course of the vessel about one centimetre, where the lumen of the vessel became slightly greater, and its walls resumed their normal thickness. The thrombi of the vena cava were more highly organized than were those in the jugulars. These specimens are interesting as showing the process of organization of thrombus. All the sections exhibited transverse sections of, comparatively speaking, large vessels, some of which, doubtless, were in direct communication with the blood in the thrombosed vein. In some of the specimens extremely delicate vessels could be traced, whose course extended from a consider-

able distance within the walls of the vessel to far into the clot. There were new vessels which had been developed from vessels in the walls of the vein itself. Baumgarten considers this alone to be the true source of the vascularization of clot. The results of the autopsy, I need scarcely say, were quite different from what had been expected. The symptoms during life pointed to obstruction of the large veins, due to some growth or aneurismal dilatation exercising pressure on the vessels. Phlebitis affecting both jugulars was easily recognized, and treated accordingly, and had been considered as the effect of pressure on vessels below. That there had been an inflammatory condition of the jugulars and large veins below there was no doubt whatever. The complete absence of any growth and the condition of the walls of the vessel at its origin point rather to a primitive phlebitis beginning in the adventitia, which resulted in structural changes in the vessel. Structural change in the intima has unavoidably associated with it more or less thrombosis. On comparing the thrombi from different regions, it will be seen that those of the jugulars were of recent formation, whilst those from the vena cava were of a much older date; the thrombus was completely organized and the vessel walls had contracted on it. The accumulation of fluid in the pleura was evidently only a slight factor in the breathlessness.

It is a debatable point whether or not the bronchial and pulmonary vessels anastomose. Cohnheim³ and Litten deny that there is any communication between the two. Virchow, Hippolyte-Martin, Rindfleisch, Kuttner, and others are even more positive in asserting to the contrary. Hippolyte-Martin⁴ says, "After having rapidly opened the thorax in a guinea-pig and placed a ligature upon the trunk of the pulmonary artery at its origin, we have injected Prussian blue gelatine through the abdominal aorta; the coloring matter could penetrate into the pulmonary vessels by the bronchial arteries." He adds, however, "Upon section of the organ it was easy to see that the alveolar capillaries were but partially injected." I think we may accept the view that the vessels do communicate; we would then have these vessels considerably dilated, and this permanent dilatation means really thickened walls; conditions less favorable to the interchange of gases in the pulmonary capillaries and consequently accounting for the dyspnoea; the thickened walls of the septa would also impede free interchange of the gases. Another condition which, on purely physical reasons, I believe to have been a sufficient cause for the great distress in breathing is the permanency of the foramen ovale which was present in this case. This abnormality may exist without any disturbance of circulation—that is, so long as you have the auricle filling from above, the direction of this current being over the annulus ovalis will keep it in contact with the fossa ovalis, thus closing the orifice and preventing blood passing directly from the one auricle to the other. As soon, however, as the blood coming from the superior vena cava is shut off, the blood rushing upward from the inferior vena cava must naturally get beneath the annulus ovalis into the left auricle, which would be a most unfortunate circumstance for an over-distended pulmonary circulation.

To account for the fluid in the pleura, before any inflammatory attack developed itself, we will examine a little more minutely the vessels implicated. Thrombi were found in the superior vena cava, right and left innominate veins, internal jugulars and inferior thyroid veins. This would

⁴ Archiv de Phys., t. vii.

involve, besides the vessels of the head and neck and both arms, all of which were cedematous for a considerable time, four large intercostal veins on the left side, one intercostal on the right, the left bronchial vein, besides the internal mammary and some other smaller vessels, all of which reached the heart through the superior vena cava; thus, most of the blood from the left thoracic cavity emptied itself into the left innominate vein. Now, Sotnischewsky⁶ proved by experiments at the Pathological Institute of Leipzig four years ago, that tying the veins is not of itself sufficient to cause edema; that it requires that the vessel should be in a thrombosed condition in order that no possible collateral circulation could relieve the congested vessels. I regret when the autopsy was made, that I was not aware of these facts. However, the autopsy affords quite sufficient evidence of the cause of this effusion. The fluid blood from the regions in which the thrombosed vessels lie must reach the heart by way of the inferior vena cava; so must, also, certainly a portion, if not all, of the blood of the bronchial vein. It can only do so by widening of the inosculations of the superior intercostals with the fifth and inferior intercostals and azygos veins on the left side; on the right side by way of the azygos major; also by the superficial epigastrics and possibly the renal vessels on both sides.

Whatever the nature of the initial lesion may have been, I think there can be little doubt the lifting a heavy weight twelve months previous to entering the hospital was associated with it, and that it was of an inflammatory nature in the region of the vena cava—probably commencing in the adventitia—the inflammation assuming a chronic character. With the further progress of this inflammatory condition thrombosis occurred, as yet not completely obliterating the vein. The coughing up of blood I would suppose to have been the result of strain in this way:—The calibre of the vena cava has been diminished by conditions just described. Some blood would still be streaming through it, but in greatly diminished quantity; the upward current from the inferior vena cava would be much the stronger of the two. With the slightest extraordinary effort it would get beneath the annulus ovalis and permit of the blood entering the left auricle, and thus delay the blood in the lungs. Rupture of some of the capillaries in the lungs could easily take place.

If my theory be correct, a history of the succeeding pathological processes becomes a simple matter. We know that when we have coagulation taking place in a vein as a result of injury it very frequently causes other coagula to be formed, and eventually inflammation of the walls of the vessels, or should any inflammation have been previously present, these processes are still further intensified. The symptoms which were present point conclusively to at least two, if not three, well-marked extensions of the affection which might be interpreted thus:—As soon as the primary lesion caused closure of the vena cava, thrombosis occurred up to the vena innominata, causing disturbance of circulation, cyanosis, and other symptoms. This condition would be gradually relieved by collateral circulation, by way of the intercostals and azygos veins, and also by the internal mammary and superficial epigastrics; the phlebitis continuing, thrombosis would extend higher up, consequently the blood would have to seek other channels than those established by way of the internal mammary and intercostals, etc., to reach the azygos veins.

Montreal.

THREE CASES OF CILIA IN THE ANTERIOR CHAMBER.

By CHARLES E. GLASCOOTT, M.D.,

Surgeon to the Manchester Royal Eye Hospital.

A CASE was published in *THE LANCET* by Mr. Williamson, of the Newcastle Infirmary, in which a few lashes were removed from the anterior chamber after a presumed residence there of about three weeks. As very few cases of a like nature are recorded, it occurred to me that it might be desirable to supplement Mr. Williamson's case by the description of three cases in which I have found cilia in the anterior chamber, at periods varying from one week to three years after injury to the globe. It is worth noticing that in all three cases the rupture of the cornea had been caused by the impact of a blunt-edged substance striking from above; the lashes in all my cases, on examination, were found to be entire, as if they had been forcibly pulled out by the roots; their exit from the anterior chamber with the first gush of aqueous humor had no doubt been prevented by the elasticity of the edges of the cornea wound closing upon them, by the prolapse of iris, and by the subsequent healing of the wound. It is interesting to note that in two cases an attempt had been made by nature to extrude the foreign bodies through a fistulous opening in the wound, in the axis of their longest diameter. These cases also point to the advisability of using lateral or oblique illumination in the examination of all cases of injury to the eye as a matter of routine, for without its aid the cause of the irritation would certainly have been overlooked.

On Jan. 12th, 1870, G. G—, a young engineer, was in the act of shutting the door of a broken lamp which was swinging in the wind, when a large, irregular piece of plate glass fell out and injured his right eye, cutting the globe across at its outer sclero-corneal junction. He at once put his handkerchief to his eye, and keeping it firmly compressed he hastened to the Salford Hospital, where he states he was treated by means of cold water compresses, without the lids being opened. He suffered much pain the night of the injury, and slept very little. On the 17th he came under my care at the Royal Eye Hospital, when I found that there was an almost horizontal wound two lines and a half in length, at the outer sclero-corneal junction of the right eye, the lips of the wound being in close apposition, except at the outermost margin, where there was a small prolapse of iris. The anterior chamber was quite full of blood, so that the amount of injury to the deeper structures could not be made out. Atropine was instilled several times, with the effect of making him "feel much easier," and a pad and compressive bandage were applied. He continued the use of atropine drops and bandage for about three weeks by which time most of the effused blood had become absorbed, and the wound had healed, leaving a minute fistulous opening close to the outer angle. Vision was reduced to counting fingers at two inches and a half. Three days later I saw him again, when he complained of a pricking feeling in his eyelids, as if there was something in his eye. Suspecting atropinization, I everted his lower lid, and was about to examine the upper one for granulations, when I observed a small, black point projecting through the fistulous opening referred to above. On seizing it with a pair of forceps, it readily came away, and the patient expressed himself relieved. On examining the foreign body it proved to be an eyelash, slightly swollen by its immersion in the aqueous humor. This led me to

⁶ Virchow's Archiv., Bd. lxxvii., S. 85.

examine him ophthalmoscopically, and by oblique illumination; by the latter method I was enabled to see a number of cilia bridging across the anterior chamber, and resting against the anterior surface of the lens. By some manipulation I induced a few more of the cilia to present themselves at the wound, and drew them out with the forceps. They were mostly adherent to one another in bundles of twos and threes, and I succeeded in removing fourteen; I then used atropine, and reapplied the bandage. Since their removal he has had no lacrymation or uneasiness whatever; the wound has closed, and he says his sight is returning. Two months later the site of the wound was occupied by a dense linear cicatrix, and although the lens capsule was partially opaque, he could make out letters of No. 6, Jaeger, at five inches. I may here remark that the affected eye was an amblyopic one before the accident, and squinted outwards, so that he feels very little inconvenience from the result of the injury. The patient stated that his eye was perfectly comfortable, and I found there was no tenderness on pressure. I have just seen my patient after a lapse of twelve years, and I find the eye unchanged. His vision is No. 6 with the right eye, the refraction being myopic, and the sight of the left is 1 6-6. Although the wound was over the ciliary region, he has had no irritation in the eye, or tendency to sympathetic trouble.

My second case occurred in the person of M. S—, a young mill hand, who was injured by a young man throwing a piece of a broken bobbin at her from across the room, hitting her on the right eye, causing an irregularly shaped wound across the cornea, with a slight prolapse of iris. The wound healed rapidly under ordinary treatment, with a very slight anterior synechia. She has had several attacks of irritation in the eye, with increased tension and bulging of the wound, since, when she attempted to work, which caused her to return to the hospital. On examining the eye by focal illumination four months after the accident, I found two lashes lying saltierwise in front of the upper quadrant of the iris, the lower limbs of the St. Andrew's cross formed by the lashes being directed somewhat forward, and standing upon the posterior surface of the wound. I determined to attempt their removal, and proceeded to make an upper iridectomy, so as to include the anterior synechia as well. I managed to remove one of the lashes by means of the iris forceps, but the other disappeared, no doubt having become entangled in a blood-clot, and thus sponged away, the hemorrhage from the cut surfaces of iris being pretty copious. The iridectomy wound healed in a few days, and the tendency to corneal staphyloma was reduced. Eight months later she visited the hospital, and reported the eye as having been perfectly quiet since the removal of the lashes, and that she had resumed her work at the mill. Vision with injured eye is now 8 6-00 c. + 8 sph. = 1 6-18. I have no doubt that the distant vision could have been further improved if the corneal astigmatism had been corrected.

Rachel B—, my third case, aged thirteen, received a blow on the right eye with a rough piece of wood, a portion of a clog sole, three years before I saw her, which wounded the lid, and ruptured the cornea above and to the inner side, causing traumatic cataract and prolapse of iris. The corneal wound healed in a month, but the eye always remained "weak and watery," and three weeks before I saw her the eye had become inflamed and painful. When I first saw her there was a dense cicatrix in the upper and inner side of the cornea, bulging forward and pierced in the centre by a minute fistulous opening through which a lash projected for about two-thirds of its

length. The pupil was blocked by a dense capsular remnant, and there was a large anterior synechia. I took the girl into the hospital and performed an iridectomy downwards and inwards, removing three lashes, which were sticking in the stretched iris. The capsular remnant I was also able to remove by means of a pair of straight iris forceps. The wound healed in a few days, and the staphylomatous bulging subsided. I saw the patient recently, and found vision to be No. 6 c. + 2 and c. + 4 = 6-18. There has been no recurrence of pain or irritation since the removal of the lashes.

Manchester.

THREE CASES OF LISTERIAN OPERATION FOR THE RADICAL CURE OF INGUINAL HERNIA.

By EDWARD LAWRIE,

Professor of Surgery, Lahore Medical School.

In the following cases the antiseptic principle was strictly carried out.

CASE 1.—A European gentleman, aged forty-four, from Phillour, consulted me on December 7th, 1882, on account of double inguinal hernia. The protrusion on the right side had existed since 1863, and that on the left since 1865. On December 11th I performed a modification of Professor K. McLeod's¹ (of the Calcutta Medical College) operation for the radical cure of the hernia on both sides. Commencing with a free exposure of the external abdominal ring, and of the hernial sac and spermatic cord for an inch or more below it, the sac was dissected clear of the cord and transfixed close to the ring with long thick double catgut ligatures, which were tied on each side. The sac was then cut across below the ligatures. The pillars of the ring were next brought together with the ends of the ligatures which held the stump of the sac. A Wood's needle was passed first through the outer end and then through the inner pillars of the ring, and threaded and withdrawn with the ends of the ligature on the outer side of the stump, and the same process was repeated on the inner side. The four ends, now holding the pillars of the ring, were tightly tied in pairs on each side of the stump of the sac, and the ring was thus effectually occluded without any undue pressure on the cord. The ligatures were cut short, and the external wound sutured with thin catgut. The patient left Lahore cured and not wearing any truss on Jan. 13th. Both wounds healed by the first intention, though the patient's recovery was delayed by a severe attack of dysentery, which developed itself on the day following the operation.

CASE 2.—A gentleman, aged forty-nine, from Amritsar, consulted me on December 30th, 1882, on account of an inguinal hernia of the right side of six years' standing. The operation was performed on Jan. 1st. The wound healed throughout without inflammation, and the patient got up on Jan. 8th. On the 14th he left for his home cured, and able to walk freely without a truss.

CASE 3.—A gentleman, aged thirty-seven, was sent to me from a distant station on Jan. 3rd, 1883, with a tumour of the right testicle and right inguinal hernia. The hernia dated from July, 1872. The tumour was as large as the closed fist, of three months' growth, and of soft consistence. The operation was performed on Jan. 5th. The abdominal ring and tumour were fully exposed by a free incision. The hernial sac was found to be

¹ Vide Indian Medical Gazette for October, 1881.

congenital, and contained a mass of omentum, which was adherent to the upper surface of the tumour. The neck of the sac and its contents were transfixed *en masse* with double catgut, which was tied on each side immediately outside the ring. The sac, omentum, and tumour were amputated half an inch below this point, and the ring, with the thick stump in the centre, was occluded in the same manner as in Cases 1 and 2. A horsehair drain was employed and removed on the fourth day. On Jan. 12th the wound, with the exception of a single stitch-hole at the top, was soundly healed. The patient left Lahore on Jan. 20th, 1883, well and not wearing a truss. (The tumour proved on examination to be a soft carcinoma. It weighed fourteen ounces and was confined to the epididymis. The spermatic duct was healthy.)

The operation I have adopted for the radical cure of hernia differs from that described by McLeod in the *Gazette* in detail, though the principle is the same. The modifications of McLeod's procedure, which I consider important, are briefly (1) non-excision of the sac and (2) occlusion of the ring, with the ends of the catgut employed for its transfixion and deligation. In this way the wound, in uncomplicated cases, is small, the catgut cannot slip off the sac, and the correct position of the stump in the centre of the ring is secured. I have recently operated in this manner on nine cases of hernia in hospital, in all of which the results were as good as in those reported. Under proper antiseptic management, without which the operation would be impossible, the wound heals at once, and consolidation of the ring is complete in from eight to ten days.

Lahore.

ON CHEYNE-STOKES' RESPIRATION.

By F. M. PUDDICOMBE, L.R.C.P. Lond., etc.

SEEING that the above subject has been brought before the notice of the profession once more by Dr. Paterson in *THE LANCET*, I venture to submit the particulars of the following case which has been under my care for some time past, and which presents several points worthy of notice.

S. E—, aged sixty-four, deaf and dumb, a brewer's laborer, with no family history, and no history of the patient's past life can be traced, with the exception that he was given to fits of intemperance. On January 29th he was brought to the Teignmouth Infirmary in a state of insensibility, the limbs motionless, and the body cold; pupils somewhat contracted but answered to light, and the pulse was slow but weak. He had been found in this condition in a yard adjoining the brewery about an hour previously. Hot bottles were applied to the feet, he having been put to bed, and soon he was able to move slightly, when it was found that he was paralyzed on the right side. No reflex movements could be produced on tickling the right foot. A short time after this he resisted all attempts to feed him, and we were obliged to use force during the rest of the day in order to make him take small quantities of nourishment.—30th: Has passed a restless night, snoring loudly whenever he dropped to sleep for a few minutes. He has passed some urine in the bed, but seems to have some control over his bladder. Has taken beef-tea and milk willingly, but latterly it has returned. Has had an ice-bag applied to his head and blisters behind his ears. Although there seemed to be some improvement this morning, he is decidedly worse to-night, and is very restless.—31st: Sickness continues. Pulse is full and slow (56) this morning. Has used a bottle to pass urine in. Has retained a small quantity of

beef-tea mixed with ice and lime-water. Bowels confined. Temperature 99.8° this evening.—Feb. 1st: Sickness stopped; temperature 98.6°. Seems better; appears to be conscious. The bowels have acted after an enema. Five grains of the bromide of potassium to be taken every five hours.—2nd: The same.—3rd: Rather lower this morning, but takes beef-tea and milk willingly. This evening, for the first time, my attention has been drawn to a most peculiar form of breathing. It much resembled that related by Dr. Paterson; the ascending and descending respiratory acts being well marked; the crisis, so to speak, consisting of a long-drawn, violent, and noisy respiration. Each breath was accompanied as a rule with stertor, even to the last of the descending series, the noise of the last breath somewhat resembling that made by the escape of the last water from a bath by a waste pipe—a peculiar sucking noise. The pause would then take place, and would last from ten seconds to a minute, the duration varying greatly; the breathing would then recommence, softly at first as a rule, and then louder and louder, but sometimes it would begin again with a sudden violent and noisy effort. The number of ascending and descending respiratory acts numbered on an average seven to ten of each.

It would be superfluous to give a detailed account of the daily progress of the case. Suffice it to say that no material improvement took place; indeed, little or no alteration could be observed for many days, until, on the 19th, when, though he seemed on the whole to be much weaker, reflex movements were readily induced by tickling the feet.—24th: The pauses still continue, though not so markedly as before; they have been observed several times during the daytime for the past few days, but only when sleeping, whereas at first they were only noticed at night.—26th: The patient is much weaker. He can only be made to swallow with difficulty, and each attempt is attended with violent coughing. Only once or twice has the peculiar respiration been observed during the past twenty-four hours.—27th: The patient is very much worse, and apparently sinking fast. The character of the respiration is entirely changed; there are no pauses, but he breathes with stertor, fifty respirations to the minute. All the patient's urine since the previous day has been passed under him, and he seems quite unconscious. Feeding (beyond wetting his lips with a feather dipped in milk) is out of the question. At 10 p.m. I was called by the nurse, who said the patient was dying. His respirations were sixty in the minute. The pulse could not be felt. The breathing gradually became slower and weaker, and after a couple of pauses of about a minute each (such as may often be noticed in dying people) it finally stopped. The temperature of the body at the time of death was 102.6°. The urine could not be collected for the past two days.

Before giving an account of the autopsy I will mention several facts in connection with the case, which for convenience, I have hitherto omitted. In the first place, the pauses rarely were noticed in the daytime, and then only during the last few days of the patient's life, but during the night they were extremely well marked, coming on with regularity about eight or nine in the evening, and ceasing towards morning. Secondly they never occurred when the patient was awake, but he would drop off into a nap, and after a minute or two, more or less, the peculiar form of respiration would commence. Thirdly, towards the termination of the pause twitchings would often, but not always occur; these were noticed, of course, on the sound side of the body, also occasionally movements of the abdominal parietes might be noticed.

Fourthly, shaking would not at first break the pause, but if continued it generally took effect. Sometimes on shaking him he would give a short inspiration, and again pass into a state of apnoea. On auscultation the heart sounds, which seemed normal, but rather faint, could be heard plainly alone, and in no way irregular. The pulse could be felt at the wrist beating strongly, and differing in no perceptible degree from that which could be felt during the breathing period. The commencing respiration sounded most peculiar, and could be heard through the stethoscope generally a second or two before there was any outward or visible sign of it. The urine during the early part of the case showed only traces of albumen, and had a specific gravity of 1025, acid reaction. During the latter period of the case there was a great quantity of albumen, and the urine was more scanty. There was no dropsy of any part of face, body, or legs. With regard to remedies, I found none to have much effect. Bromide of potassium and chloral hydrate were totally inert, and the more he slept the worse he was. Nitrite of amyl, on being held to his nostrils, stopped the symptoms temporarily, but only by causing him to wake up, which he invariably did after it had been held to his nose for seven or eight seconds. The nurse reported that on several occasions he was more quiet after its use for the rest of the night, but on others he was as bad as ever.

The following is an account of the post-mortem examination made on the body the day following death. On removing the skull-cap and dura mater a quantity of fluid escaped, and the posterior surface of cerebrum and cerebellum was congested, especially on the left side. The pia mater was much injected. The substance of the cerebral hemispheres differed little, if at all, from that seen in health. On cutting into the ventricles the left was greatly distended with bloodclot, and the right contained a small clot and a great quantity of serous fluid. On washing away the clot the corpus striatum and other portions of the floor of the left ventricle were found to be much softened and disintegrated. The pons and medulla, as far as could be seen with the naked eye, were perfectly normal and healthy, and, though covered with injected vessels of the pia mater, it was white and healthy on being cut into. There was no softening or disease of any kind apparent in these latter parts. The above were the only lesions to be found in as careful an examination of the contents of the cranium as it was in my power to make. The lungs were congested and oedematous. There was but little fluid in the pericardium. The heart was hypertrophied but little if at all dilated, and the walls were firm and looked healthy, showing no evidence of fatty degeneration that could be detected with the naked eye. The aorta was of large size, but showed no atheromatous patches. There was no valvular disease in the heart, but I found on opening the right ventricle two growths, the one about three-quarters of an inch across, embedded among the columnæ carneæ, and another about an inch in length and half an inch in diameter, attached by a pedicle, and hanging from the wall into the cavity of the ventricle. I also found a smaller growth in the left ventricle, attached to the columnæ. The other viscera were healthy, with the exception of the kidneys, which were both diseased, the right especially so. The granular condition was shown to a slight extent; but the principal point for notice was the presence of a number of cysts varying in size from a hemp-seed to a small marble, and containing a yellow transparent fluid. These were principally found in the cortical portion. The capsules were

easily removed, but the kidney was torn at one or two points.

The above is only a poor description of the case; but I hope it may have presented some points worthy of notice, and which may be acceptable to those taking an interest in the subject.

Teignmouth.

FRACTURE OF THE PARIETAL BONE; ATAXIA; RECOVERY.

By JOHN HOSACK FRASER, M.B. Edin.,

Late Resident Physician to the Edinburgh Royal Infirmary.

THE following is the history of a most interesting case, which has recently come under my care, and which appears to me to be worthy of publication.

About two years ago, M. W—, aged forty-five, was engaged at work when a brick fell on his head, from a height of twelve feet, inflicting a fracture of the posterior superior portion of the right parietal bone. In the course of three weeks he had so far recovered from the effects of that accident as to be able to resume work. For the next fifteen months the only symptom from which he suffered to indicate disease of the brain was occipital headache. About seven months ago he became depressed, taciturn, and apathetic, and complained of giddiness, amblyopia, diplopia, deafness, and loss of memory, from which it was manifest that he was the subject of a grave form of brain disease. A few months later his gait became unsteady and tottering, and his hair was becoming rapidly grey. When he walked he had an inclination to fall forwards or backwards; at other times he moved in a peculiar spiral manner, describing the so-called "circus" movements. About the end of March this ataxia became so much worse that he was unable to sit or stand. Urgent vomiting, a slow and irregular pulse, and drowsiness, accompanied with sleeplessness and delirium, set in. This was his condition when I saw him on March 29th, 1883, and, after making a careful examination on that occasion, I pronounced him to be suffering from a tumour of the cerebellum. Ophthalmoscopic examination revealed double optic neuroretinitis. The right pupil was dilated and semilunar in shape; the left was normal both in size and form. His sensations, sensibility, and reflexes were perfectly normal, and there was an entire absence of motor paralysis.

My reasons for localizing the disease to the cerebellum were as follows:—(1) The persistent occipital headache. This probably pointed to a stretching of the tentorium. (2) Vertigo. (3) Loss of coördination. (4) Amblyopia and diplopia. (5) Deafness. (6) Vomiting, and slowness and irregularity of the pulse. These two last-named symptoms probably pointed to an irritation of the pneumogastric nerve. The slowness and irregularity of the pulse varied distinctly with the headache, being most marked when the headache was most intense, and *vice versa*.

As to treatment, before adopting any remedial measures, it was most important to decide the question of syphilis. He denied having had that disease, but, on making an examination, I found a cicatrix on the glans penis and enlargement of the glands in both groins. I ordered him one-sixteenth of a grain of the perchloride of mercury and ten grains of the iodide of potassium three times a day, and at the end of a week I was surprised to find the great improvement that was apparent in his condition. The vomiting, drowsiness, headache, and delirium had left him; his memory was decidedly improved; and his hair, which was previ-

only grey, was fast returning to its natural brown color. There was, however, no improvement in his coordination. Four days later I found him comfortably seated in his chair, and he could stand with his feet widely apart, but could not walk without tottering and falling. A week later I was much pleased to find that he could stand steadily with closed eyes when both feet were brought closely together, and walk remarkably well.

Birmingham.

THE TREATMENT OF DIABETES INSIPIDUS BY ERGOT.

By T. HAMMOND WILLIAMS, L.R.C.P. Ed., etc.,
Senior Assistant Medical Officer to the Town's Hospital and
Asylum, Glasgow.

THE following notes may be interesting as corroborating recent research in the treatment of this previously intractable disease.

During a short period as resident assistant in the Glasgow Royal Infirmary, I had the opportunity of seeing several cases treated with valerian, and with very discouraging results (Trousseau). Galvanism was equally ineffective. Keeping in mind that there must be increased blood-supply to the kidney, and as this is controlled by the inhibitory branches of the sympathetic, the treatment is obviously one of decreasing the blood-supply through that channel. Of the many agents which act thus, ergot in its various forms seems the most potent. Two cases having come under my observation, the feasibility of the above treatment was suggested.

Margaret Mc—, aged fifty-one, widow, washerwoman, was admitted Oct. 21st, 1881. Her trouble commenced about four years ago. She had enjoyed fair health previously, except an attack of small-pox in her youth. Has had seven children. Was rather intemperate in her habits. The first symptom was thirst, of which she took little notice, until the frequent calls to pass urine compelled her to seek advice. When admitted her urine amounted to 280 ounces daily; sp. gr. 1002, clear, limpid; deposit of phosphates; no albumen; no sugar. Her appearance was pale and emaciated. Heart's action weak and fluttering. Complained of shifting pains, which gave her great annoyance. Skin was extremely parched, and spirits much depressed. Appetite voracious. Bowels regular. Two drachms of the fluid extract of ergot were administered thrice daily, combined with digitalis to steady the heart's action. Under this treatment the improvement was marked and striking, the quantity of urine excreted diminishing in three weeks to 140 ounces. This treatment was continued for another month, with the result of further reducing the quantity to eighty ounces; sp. gr. 1015. The pains disappeared after being only a fortnight under treatment. When the patient felt herself so much improved she left the hospital, notwithstanding my efforts to induce her to remain, promising to return if the symptoms were renewed. I have not since seen her.

Mary —, aged forty-nine, widow, hawker. As in the above case, the first symptom which attracted attention was increasing thirst, afterwards frequent nightly calls to pass urine, of about four months duration. When seen her bodily condition was good, appetite fair. Had history of "weak turns" of long standing, and repeated attacks of bronchitis. Heart sounds weak and distant, pulse soft and compressible. Shifting neuralgic pains, with vertigo, were much complained of, which no treatment seemed to benefit. Tem-

perature normal; family history good. Urine: sp. gr. 1005; acid reaction, no albumen, no sugar, a trace of phosphates. Daily quantity of urine passed was 300 ounces. After failures with tannic, benzoic, and phosphoric acids, I again prescribed ergot, also in combination with digitalis, reducing the quantity of urine in twelve weeks to seventy ounces; sp. gr. 1018.

Although the dose of ergot prescribed was large, no ill effects were produced, except constipation, to counteract which an occasional purgative was given. The disappearance of the neuralgic pains during the progress of treatment seems to confirm the general idea of the nervous origin of the malady. The disease in the above cases was not traceable to any assignable cause or hereditary taint.

Glasgow.

FIVE SUCCESSFUL CASES OF TRACHEOTOMY FOR CROUP;

WITH REMARKS ON THE CONSTRUCTION OF THE TUBES AND THE DIFFICULTIES IN THEIR FINAL REMOVAL.

By JAMES L. LITTLE, M.D.,

Professor of Clinical and Operative Surgery, New York Post-Graduate Medicine School; Professor of Surgery, Medical Department of Vermont University, and Surgeon to St. Luke's Hospital, New York.

BUT little attention has been called to the dangers and difficulties of permanently removing tracheotomy tubes after tracheotomy and the re-establishment of the natural respiration. My remarks in this paper will be confined entirely to cases where this operation was performed on patients suffering from croup. During a period of twenty years, though performing it a great number of times, I had but one successful case until the fall of 1879, when it was my good fortune to have four consecutive cases which were successful.

CASE 1.—In this case the operation was performed for diphtheritic croup, and the tube was removed on the sixth day without any unpleasant symptoms.

CASE 2.—In September, 1879, I performed the operation on a boy four years of age, the ordinary fenestrated silver tracheotomy tube being used. Three weeks after, the child being in an apparently good condition, it was thought advisable to remove the tube; the inner one was removed, and the opening of the outer was corked up for fourteen consecutive hours. During this time the patient breathed through the mouth without the slightest difficulty. Dr. Frank Anderson, United States Navy, who had the case in charge, then removed the tube and for two hours and a half no trouble whatever occurred, but at the end of that time the respiration became suddenly obstructed, and in about one minute was completely arrested. Dr. Anderson was fortunately at the door of the room when this happened, but before the tube could be found, it having been mislaid, the child was unconscious. He quickly reintroduced the tube, using some force, as the opening had already contracted, and with the aid of artificial respiration and inflation of the lungs through the tube, the respiration became re-established. Bloody and frothy expectoration took place through the tube during the remainder of the day. On the following day I removed the tube and carefully examined the wound with the aid of the head mirror. Around the external margin a considerable number of exuberant granulations could be seen. The tracheal margin of the wound was inspected with difficulty, as there was considerable thickening of the soft parts over the trachea. A number

of whitish granulations could be seen apparently connected with the upper margin of the tracheal wound. Several attempts to seize them with a slender pair of forceps failed. An attempt was then made to apply subsulphate of iron, Monsel's solution, by means of a feather, as recommended by Jacobi, to these granulations. The tube was kept out for about four minutes, when the child becoming somewhat embarrassed in his respiration, it was replaced. The tube was removed every third day by Dr. F. Anderson, and an attempt made to touch the granulations with Monsel's solution. Symptoms of asphyxia would always occur in a few minutes after the removal of the tube. On November 1st, the tube being taken out by Dr. Anderson in order to make an application of the iron, the breathing again suddenly became arrested and the child became cyanotic before it could be reintroduced. From this time the outer tube was allowed to remain for several weeks without being disturbed. The mucus which was expelled from the opening was almost always stained with blood. On careful and repeated examinations it was found that the fenestra of the tube did not completely enter into the trachea; when the inner tube was removed, reddish granulations could be seen in the track of the wound, protruding into the dorsal opening. For this reason it was thought advisable to try a non-fenestrated cannula, and one was procured, having the lower end beveled from before downwards and backwards, so that the sharp extremity should not impinge against the anterior wall of the trachea. From the time of the introduction of this tube the condition of the wound rapidly improved. The external granulations seemed to dry up, and at the same time the child began to breathe through his mouth, while the mucus discharged from the tube was no longer stained with blood. Four months after this operation, I found the child much improved in general health. He could breathe freely through his mouth, was able to talk in a loud and clear voice, could blow and whistle, the air passing upwards alongside the tube. The edges of the external wound were entirely healed, and the thickening of the soft parts had disappeared. In order to make sure of the child's ability to breathe without the aid of the tube, I closed its opening with a cork, and allowed it to remain about half an hour; during this time the child breathed freely through the mouth. I then determined to remove the tube and watch the result. In order to be ready for any emergency that might arise, I laid out my instruments, and arranged to remain in the room with the child until morning. The tube was then removed, and the wound left uncovered, air passing freely in and out during respiration. The child soon fell asleep in the nurse's arms, and was placed in his bed. Two hours after air ceased to pass through the wound, and it had contracted to a very small opening. The child passed a good night, not waking till morning, his respiration being free and noiseless. From that time no difficulty has occurred.

CASE 3.—On April 8th, 1880, I was called to perform tracheotomy on a patient of Dr. Stronach's, of New York, the case being one of diphtheritic croup in a girl three years and four months of age. I used a non-fenestrated tube of five millimetres in diameter. The child made a rapid recovery; granulations occurred around the margin of the external wound, and, on being treated with occasional applications of nitrate of silver, rapidly disappeared. At the end of five weeks the edges around the external wound had entirely healed; the child breathed naturally through the mouth and her articulation was almost perfect. I removed the tube and the wound closed rapidly, so that at

the end of an hour no air could be detected passing through it.

CASE 4.—On May 7th, 1880, I was called to see a patient of Dr. Griswold's, a girl about four years of age, who had suffered from symptoms of membranous croup for three days. The child was cyanotic and tracheotomy was performed at once. The recovery was rapid and without any unusual symptoms. No membrane was expelled from the tube. Two weeks after the child could not breathe freely through the mouth with the tube closed, and therefore it was allowed to remain *in situ*. In April, 1881, eleven months after the operation, I found that the tube was still in position. The child breathed freely through the mouth, and her voice was loud and clear. I removed the tube, and in two hours no air could be felt coming through the wound.

CASE 5.—In January, 1881, I was called to see a patient of Dr. Cypert's, a girl four and a half years of age, suffering from membranous croup. In this case pieces of the membrane had been expelled from the trachea. The dyspnoea was very severe, and immediate operation was necessary. On the eleventh day after the operation, upon removing the tube for the purpose of cleansing, I found difficulty in replacing it; it was therefore left out and no untoward symptoms occurred. For two or three days before the removal of the tube, the child was able to articulate loudly. Great improvement took place in this respect, however, after the removal of the tube.

In the first case the obstacle to the re-establishment of the natural respiration was due to the presence of granulations around the edge of the tracheal wound, which evidently were held down while the tube was in position. Upon the removal of the tube they formed an obstruction to the passage of air through the larynx as soon as the tracheal wound contracted. Dr. Jacobi, in a paper on "The Pathology and Treatment of Croup," published in the *American Journal of Obstetrics*, May, 1868, called attention to the same condition interfering with the removal of the tube in several patients upon whom he had operated for tracheotomy. Mr. Thomas Smith, in a paper on the "Obstacles to the re-establishment of Natural Respiration after Performance of Tracheotomy," published in the *Medico-Chirurgical Transactions*, vol. xlviii., also relates several cases in which the presence of these granulations prevented the removal of the tube. In Dr. Jacobi's and in my own, a fenestrated tube was used, and I infer from the description given by Mr. Smith that these tubes were used in his cases. In my second case, where a closed cannula was used, and allowed to remain in four weeks, no granulations were seen, though carefully looked for. In my third case, where the tube remained in eleven months, a non-fenestrated tube was also used, and there would probably have been no difficulty in its removal, after a few weeks, if other troubles had not intervened. These cases seem to prove that the fenestra which is found in nearly all the tracheotomy tubes made by American instrument makers, and which is for the purpose of testing the ability of the patient to breathe through the larynx when the tube is closed, is not only useless but injurious, probably causing by its irritation the growth of these granulations. Dr. Lewis A. Sayre reported a case before the Medical Society of the State of New York, in 1864, in which fatal hæmorrhage took place, on the seventh day, after the operation, in consequence of a slough through a large vein in the neighborhood of the wound, caused by the pressure of the edges of the fenestra of the tube.

In the paper already referred to by Mr. Thomas Smith a letter from Trousseau is published, in

which he says, "I advise you whenever you can to leave a closed cannula in the trachea until the child has breathed for ten days in a natural manner. The cannula, with a dorsal opening, is a useless and often dangerous instrument, for, if you compare the calibre of the cannula with that of the trachea, you will see that the section of the trachea is more than double the area of that of the cannula. The air, therefore, can pass freely between them. On the other hand, the tissues project through the dorsal opening of the cannula, and thereby the inflammation is kept up." In my second case, after the granulations had disappeared, the closed cannula was no hindrance to the child's breathing in a natural manner. His voice was as loud and distinct before the final removal of the tube as after; in fact, I could perceive no difference whatever. One other point in connection with this case, which I did not refer to in the history, is this: the first tube which was used had an immovable collar. The non-fenestrated tube had the usual movable collar, which, allowing a considerable degree of motion, prevented a certain amount of irritation during swallowing, coughing and other movements of the patient's neck. In regard to the size of the tube, Mr. Robert M. Parker, in a paper on tracheotomy in *Membranous Laryngitis*, published in the *Medico-Chirurgical Transactions*, vol. lxii., advises the use of the largest tube that can be got into the trachea without actual violence, for the reasons that it will afford the patient a better supply of air, and also allow the tracheal secretions to be removed with greater facility, which feature in the after-treatment of these cases he considers of paramount importance. He also advises the movable collar and the beveling of the extremity of the tube, and recommends that the tube be as short as is consistent with safety; he finally proposes a cannula in which the curve resembles the Gothic rather than the Roman arch. If a tightly fitting tube such as he advises be used, it should of necessity have a fenestra, as the air could not pass between it and the walls of the trachea. In the other cases detailed, the advice given by Trousseau was strictly followed and the tube was not removed until the voice was clear and the child could breathe freely through the mouth. I think the size of the tube should always be smaller than the calibre of the trachea. It should have a movable collar, and the lower extremity should be beveled from before downwards and backwards. I consider that the shorter the tube the better. In order to make these tubes as light as possible, I have had them manufactured for me by Mr. Tiemann, of New York, of aluminium. This does not tarnish nor

corrode like silver. The shape of the tube is here represented. I have never used the Durham tube, which has the advantage of being shortened at will. The excellent tube recommended by Mr. Bryant has this same advantage, combined with a ball-and-socket movement, which imparts mobility to the tube when in the trachea. This tube could be improved, I think, by being made of aluminium.

(9)

The conclusions that I would draw from these cases are—

1. That the tube used should be somewhat smaller than the calibre of the trachea, should have no dorsal opening, and should be made with a movable collar or ball-and-socket attachment.
2. No attempt should be made to remove the tube permanently until the patient is able to breathe freely for some days through the mouth with the tube closed.
3. That granulations around the margin of the tracheal wound will be less likely to occur if no source of irritation exist in connection with the tube.

ON DYSENTERY AND LIVER ABSCESS.¹

By **SIR JOSEPH FAYRER, M.D., F.R.S.**,
President of the Medical Society of London.

THE following example of liver abscess illustrates a form of disease which is not very uncommon among the numerous invalids who return from tropical or subtropical and malarial climates, and is more frequent in those who have resided in India or China than in Africa, the West Indies, or other colonies. I have therefore ventured to bring this case before you under the impression that it may prove of interest, and perhaps help to throw some light on a subject which, I know from experience, is not unfrequently brought under consideration in this city and its suburbs—indeed, throughout the United Kingdom generally, in almost every part of which are to be found old residents of our tropical and colonial possessions, who have returned with the seeds of disease, sown abroad, to be developed at home. Liver abscess, of course, is not confined to tropical countries; it may, and does, occur in our own islands, but is comparatively rare, and when it does happen is generally, if not always, due to septic absorption from some external wound or operation, some ulcer of the stomach, intestine, gall-bladder, or its ducts; in certain cases to ulceration or suppuration in the pelvic cavity, rectum, or ischio-rectal fossa; to fistula in ano; it may be to cancerous ulceration in the bowel or elsewhere, or to suppuration of a hydatid cyst. Such cases are generally to be regarded as of a secondary or pyæmic character, and differ widely from the large, frequently, though not always, single abscess, which, from its frequent occurrence in the tropics, has been termed by Murchison tropical abscess, though they are very similar to, if not identical with, certain dysenteric liver abscesses in which multiple foci of suppuration are due to septic absorption and constitutional pyæmic contamination from the dysenteric ulceration in the large intestine. As you are aware, tropical abscess of the liver is often seen in this country, but it is usually in the persons of those who have contracted the disease abroad, or who have developed it here as the result of disease from which they had suffered in the tropics. Now this form of liver abscess may be of different kinds.

1. The large single abscess, which is etiologically referable to the influences of heat, altered conditions of living, feeding, and the excessive or injudicious use of alcohol in tropical, subtropical, and malarial climates. The abscess is the expression of these pernicious influences, but it partakes more of the character of a local complaint, and is independent of ulceration of the bowel or of disease in any other part of the economy. In such cases the abscess is often large, is solitary, though there may be more than one, and is frequently preceded, especially in the strong and vigorous, by all the

¹ Read before the Medical Society of London, April 30th, 1883.

symptoms of active congestion and inflammation of acute hepatitis. In others, however, it assumes a more insidious and chronic form; with few well-marked symptoms, or such as escape notice, and the abscess is only revealed by unexpected bulging of the thorax, or pointing in the epigastric hepatic region, or by spontaneous evacuation of the contents through the lung, stomach, or bowels; in some rare cases it is not detected until after death, during post-mortem examination. 2. Liver abscess following, or co-existing with, dysentery, by Murchison and others was regarded as of a pyæmic nature, due to absorption of pus or septic matter from the ulcerated bowel, and therefore coming within the same category as liver abscess, originating in this country, and resembling it in its pathological character, and in being multiple. That this is the case in some instances cannot, I think, be doubted, and when the multiple abscess does occur in a dysenteric patient, perhaps no better explanation of its origin can be offered. Such a condition is, of course, one of extreme danger; indeed, it may be regarded as fatal. And here I would ask you to note the true character of these multiple abscesses, which in the outset are really no abscesses at all, but necrosis of small portions of the liver parenchyma, which, if the patient live long enough, become abscesses by suppuration occurring in the congested and inflamed liver tissue around the dead spot, which thus becomes detached and loose like the core of a boil in the centre of the cavity. I have repeatedly seen these so-called abscesses in all stages of development, from the spot of dead tissue or embolic infarct surrounded by its areola of congestion, to cavities of various sizes filled with sanies, puriform matter, and débris of liver tissue, and finally those in which real pus had formed. They are generally numerous and varying in size from a mere speck to a pea, from a marble to a walnut, an orange, or larger, and it frequently happens that they are not confined to the liver, but are found in other viscera, such as the spleen, kidneys, and lungs as well. These cases are truly pyæmic, and are, as I have said, most fatal.

It was thought by some pathologists that hepatitis and dysentery were dependent on each other. Annesley maintained that dysentery is the result of hepatitis; others that the hepatitis is the result of the dysentery. Dr. Budd, thirty-five years ago, put forth the opinion—and his view has met with much support in this country, though not in India—that liver abscess is always due to purulent absorption from the bowel, that, in fact, tropical liver abscess is pathologically identical with the liver abscess of this country. Dr. Abercrombie thought that though they co-existed they were independent of each other. Murchison, Macpherson, Maclean, and others concur in this. Martin and others thought that liver abscess was intimately connected with disease of the cæcum, but this has not been confirmed by post-mortem examination; for of 72 cases where the cæcum was affected in only 22 was there liver abscess. Moore, of Bombay, says that eight observers out of twelve record a percentage of 18, or 295 cases of liver abscess in 1,532 of dysentery cases; four others give a ratio of 39 per cent., or 52 cases of abscess out of 131 cases of dysentery; 18 per cent. is probably the correct ratio. The larger percentage is more likely due to all diseased conditions of the liver that have accompanied dysentery. Recent observations, I think, confirm this view of the relative frequency of hepatic abscess in connection with dysentery, and though in some instances of multiple abscess the condition is due to septic absorption, yet liver abscess generally must be regarded rather as an expression of the general disease than

as a direct consequence of dysenteric ulceration of the large intestine. It would appear, then, that in different climates it is more or less frequent according to circumstances, but that there is a greater tendency to it in India than in other climates. In malarious countries liver abscesses frequently occur in association with remittent fever without any ulceration of the bowel (Morehead). Macpherson gives the comparative frequency of liver abscess in dysentery as varying from 13 per cent. in the General Hospital, Calcutta, to nearly 60 per cent. (according to Annesley) occurring in Madras.

I think it must be admitted that liver abscess and dysentery are often coexistent, or that one may follow on the other very closely, and that in a certain number the hepatic abscess is due to absorption from the diseased bowel, yet that the two diseases occur frequently, may generally, quite independently of each other. Numerous post-mortem examinations have shown that liver abscess was unaccompanied by any signs of present or past ulceration in the bowels, whilst equally numerous cases of death from dysentery were unattended by abscess in the liver.

For the present I exclude from consideration the large single tropical abscess, in which there is no question of a dysenteric origin or complication, and now wish to direct attention to the question of the relations of liver abscess to dysentery when the symptoms of both diseases are present. The case I bring under your notice this evening is an example in point; and I would ask you to observe that although true dysenteric—i.e., pyæmic—abscess of the liver is of not uncommon occurrence, and is to the last degree dangerous, yet that not all abscesses of the liver complicated with dysentery is of this grave form, and that a man may have dysentery and liver abscess too, and still may recover. And here I would remark that, although I regard some of the cases of dysenteric liver abscess as merely the result of a common cause affecting alike, though independently, both liver and bowel, yet that in others I believe the liver abscess may be the consequence of direct absorption of purulent matter through the liver from the bowel; in which case the abscess may be single or double, or triple, but this is a different state of things pathologically from that general pyæmic condition which results from infection of the whole system by absorption of septic matter from the degenerative ulceration; in which cases the mischief is multiple, and often general:—

The relation of liver abscess to dysentery, I should say, might be briefly summarized as follows:—

1. The so-called abscesses which originate in local deaths of parenchyma (pyæmia, embolic deposits, or infarcts) are cavities varying in size from a mere speck to an orange, containing débris, sanies, puriform matter, leucocytes, and, finally, pus. They are seen in various stages of development, and are not necessarily confined to the liver, but occur in other viscera or regions of the body. These are truly pyæmic.

2. There is, I believe, a form of liver abscess co-existent with, and perhaps due to, dysentery, which is the result of direct absorption and transference of pus or septic matter from the bowel to the liver through the mesenteric veins. Such may be solitary, double, or triple. This is also a very dangerous form of the disease, though not necessarily fatal, as it is feared must always be the case in the former variety.

3. Dysentery, malarial fever, and hepatitis may coexist, or supervene on each other as effects of common climatic cause; it seems natural to ascribe the liver abscess in such cases to the dysentery, but it is probable that they are rather coincidences

than consequences of each other, and that the cause which affects the glandular structures of the large intestine may determine the mischief in the liver in certain climates and localities; such are obviously very different from those previously mentioned.

4. Lastly, I may just allude to the ordinary large and most frequently single tropical abscess, which is quite independent of dysentery, though, as just mentioned, it may co-exist with or follow it. Each or all of these forms may be brought under our notice in this country as the result of disease originally contracted in certain climates.

As to the extent to which hepatitis prevails in India the last statistical report gives the following information:—"In the European Army of India, averaging 57,742 men, 28,780 admissions and 1,267 deaths were recorded under hepatitis during the ten-year period 1870 to 1879. This gives an admission rate of 49.8 and a death-rate of 2.19 per 1,000. In the Army of Bengal the admission rate was 47.1 and the death-rate 2.04 per 1,000. In the preceding ten-year period the admission rate was 59.2, and the death-rate 3.31 per 1,000. A considerable reduction has thus taken place in both the admission and the death-rate, and the diminution has been pretty evenly distributed over the different sections of the Presidency. There were 7,417 admissions and 349 deaths from hepatitis in the European Army of Madras during the years 1870 to 1879, an admission rate of 67.2 and a death-rate of 3.31 per 1,000, much higher rates than those for Bengal. During the immediately preceding ten-year period the admission rate from hepatitis was 70.2, so that very little diminution has taken place in the frequency of this disease. During the period 1870 to 1879 there were 4,234 admissions and 177 deaths from hepatitis in the European Army of the Bombay Presidency, the admission rate being 40.9 and the death-rate 1.71 per 1,000, slightly less than the corresponding rate for Bengal. For the years 1863-69 the average admission rate from this disease in Bombay was 26.6 per 1,000. Hepatitis thus seems to have been more prevalent of late in the Bombay Presidency, an experience opposed to that of Bengal and Madras." The eighteenth annual report of the Sanitary Commissioner General of India for 1881 tells us that the admissions for hepatitis per 1,000 men strength for that year were: Bengal 32, Madras 39, Bombay 29. The deaths per 1,000 in the same period were Bengal 1.64, Madras 1.54, Bombay 1.52 from the same cause. It further remarks that "of the chief diseases hepatitis was the only one which during 1881 yielded a higher death-rate than the preceding year—1.60 per 1,000, against 1.34. The increase was, however, very trifling, and the admission rates are nearly identical. In Madras hepatic diseases in former years have prevailed to a greater extent than in the other Presidencies. The returns during the last two years have been very favorable, compared with the preceding ten-year period. Also that after anæmia and general debility the chief causes of invaliding in the army of India were: hepatitis, 2.96 per 1,000; dysentery and diarrhoea, 2.83; phthisis, 2.21." As a great proportion of the deaths recorded under hepatitis were probably due to liver abscess, it will be seen how large the experience of the disease is in India.

With reference to the relative proportion in which liver abscess and dysentery were coincident or combined, Dr. Waring,* in 1854, made the following notes:—

Of 300 cases of fatal liver abscess in India, in only 82 cases, or in 27.3 per cent., was the hepatitis preceded by symptoms of dysentery. Of the 300

cases, the number of abscesses was not stated in 12. Of the remaining 288, 177 had one abscess, 33 had two abscesses, 11 had three, 17 had four, 10 had from five to ten or more, and 40 had more than ten.

I will conclude what I have to say with a few remarks on the question of puncturing liver abscess. In cases of true pyæmic multiple abscess, even should the indications of the locality of these abscesses be clear, I fear no permanent benefit could be anticipated, though I think it is possible that if any one abscess caused much suffering the contents might be drawn off by an aspirating needle, and so temporary relief might be conferred. In cases where there is reason to believe that the abscess is single, and where bulging, pain, spasmodic contraction of rectus, and tenderness on pressure exist, whilst previous symptoms suggest the presence of pus, the condition may be verified by introducing a needle and examining the fluid drawn off through it. If it be pus the sooner it is all removed the better, and if it lie too deep for a free incision, by reason of the danger of cutting through the vascular liver substance, then I recommend you to draw it off through a large cannula, and, having done so, introduce a drainage-tube, taking care to exclude the entry of air; wherever it is possible I advocate a free incision, and a free drain through a drainage-tube, and for cases in which the matter lies deep I have devised a grooved cannula, on which you can enlarge the opening, and having given exit to the pus, introduce the drainage-tube. I may here remark that a certain amount of vascular liver tissue may be cut through to get at an abscess; the hemorrhage will be profuse, but it will soon cease. I believe it is very essential that the antiseptic method of treatment should be strictly attended to, and you may, perhaps, remember a case which I had the honor of relating to you some time ago, in which it was attended with complete success. I advocate exploration to ascertain the presence of pus, early evacuation whenever it can be got at, and early and free opening; drainage, and antiseptic dressing whenever practicable.

* Inquiry into Abscess of Liver. (Memorandum, 1854, p. 125.)

CASE 1. Dysentery and Liver Abscess opening through the Right Lung; Recovery.—A young civil officer, aged twenty-four, of good constitution and temperate habits, had been in India about three years and a half. When with the forces in Afghanistan in Nov., 1881, he was attacked with erysipelas of the head and face whilst suffering from an attack of climatic fever. He was recovering from this at Sibi, when he was attacked with diarrhoea, which soon became dysentery. He was then sent off to Kurrachee, where he arrived early in January, 1882, and remained there under treatment. On Jan. 23rd, having improved in health, he went to Kinari, on the coast, but on the 27th, again feeling ill, with great lassitude, depression, and pain in the side and shoulder, with loss of appetite and sickness (these symptoms supervened, it is to be observed, just as the dysenteric symptoms were subsiding), he returned to Kurrachee, and was again placed under active treatment. He had fever and a temperature of above 100°; exact degree not noted. On Feb. 13th. he was put on board a steamer and sailed for Bombay, where he arrived in three days, much improved by the sea voyage. On the 20th he left Bombay, crossed India by rail, and arrived at Monghyr on March 1st. During the month of March he had frequent recurrences of fever and pain, but contrived to do duty. Towards the end of the month he was seized one day, after riding twenty miles, with severe pain in the left side, which was attended with swelling. This was pronounced by the medical officer to be the result of a muscular strain, the consequence of a long ride on a rough, high-actioned horse. This pain and swelling subsided in about a week. He appears to have struggled on doing his duty as best he could until May, when great depression and utter inability to work came on. The medical officers reported his liver to be then much enlarged, and recommended that he should be sent to England at once. He, however, remained at Monghyr for some weeks. Towards the end of May he appears to have improved slightly, and so he continued till the middle of June, when sharp pain in the hepatic region, with difficulty of breathing, set in. A few days later, after dinner one day, a paroxysm of coughing set in, during which he brought up the contents of a liver abscess through the right lung. There were altogether five or six copious discharges of pus and blood by this channel, profuse at first, but diminishing with each attack. The last occurred on August 20th. On Sept. 4th he left India, and arrived in England in due time greatly improved by the voyage. A week after arrival he got a chill, which brought on a return of the liver pain. He was again confined to bed, and had poultices and nitro-muriatic acid. In October, being much better, he went to the south of England, and remained there till Dec. 12th, when he had a relapse. In January the right lung and pleura became affected, but he recovered (he seems to have had no further discharge of pus from the cavity), and since then has gradually regained his health and strength. In April, beyond feeling weak, he was well, and there is every reason to believe that he may be able to return to his duty by the next cold season.

This case traces in an interesting manner the passage of formation of a liver abscess and its relation to a previous attack of dysentery, which I am inclined to think was not of pyæmic character. It also gives a good idea of the difficulties and vicissitudes to which a patient may be exposed in India, and the vast extent of country over which he may have to travel before he finds relief.

CASE 2. Dysenteric Multiple Abscess of Liver.—G—, a Hindoo, aged twenty-four, was admitted Aug. 7th, and died Aug. 16th, 1880, at the Medi-

cal Hospital, Calcutta. Had diarrhoea and dysentery for a month; great pain over colon; fever; temperature ranging from 96.4° to 102.6°. Had passed sloughs with the gelatinous mucus and blood; no pain in the hepatic region. The post-mortem was made on Aug. 17th, twelve hours after death. Refer to "Tropical Diseases," page 91, for description and for Mr. Doran's examination of the liver, which is now in the College of Surgeons.

ON BEDSIDE URINARY TESTS: DETECTION OF SUGAR IN THE URINE BY MEANS OF TEST PAPERS.

By GEORGE OLIVER, M.D. Lond., etc.

I HAVE just now shown you the qualitative working of the handy tests I wish to bring before you; they belong to the series of urinary test papers which, a few months ago, I proposed as substitutes for the bottles of nitric acid and Fehling's solution at the bedside. The qualitative albumen precipitants I then brought forward have been extensively used by the profession, and I must now publicly and collectively thank many correspondents for their interesting and gratifying communications and reports. It was, until lately, my intention to have next demonstrated the several ready quantitative methods which these test papers provide us; and, after that, to have brought forward the qualitative and quantitative testing of sugar by reagents also on paper. But the pressing request of many of my friends urging me to produce the sugar test papers, and the importance of bringing them forward just now—the professional mind being unusually alive to receive impressions of new methods of clinical inquiry in this direction—have induced me to alter the order of the publication of the urinary matter still to be advanced. I therefore now wish to make a few remarks on qualitative sugar testing by means of test papers, and to reserve the quantitative methods for both sugar and albumen for another occasion. When looking round for a good and at the same time convenient test for sugar in the urine, I was particularly struck with a fact relating to indigo; and that was the presence of this intensely blue substance in a colorless state, when associated with glucose or some similar sugar; for instance, when in the juices of the indigo plants it is combined with indiglucon, which has a chemical formula only slightly removed from that of glucose; or when the dyer mixes indigo with glucose and dilute caustic alkali to produce a colorless solution, in which he immerses his fabrics, which acquire a blue color on exposure to the oxygen of the air. It then appeared to me a reasonable question to ask, Can glucose in the urine be made in some way to discharge the deep blueness of indigo, and thus to tell the tale of its presence? Experiment gave a positive answer: for when indigo was suspended—it did not dissolve—in a weak solution of soda, or in a stronger one of carbonate of soda, a test solution was obtained, which, when heated with a few drops of diabetic urine, underwent a series of remarkable changes of color—from blue to green, then to violet, to red, and finally to yellow. I longed to run the liquid containing carbonate of soda and indigo into filtering paper, and use it as a test paper; because, with carbonate of soda as the alkali, the test papers would have been more durable than with solution of soda. But unfortunately, after deposition on the paper, the indigo would not leave it. I then found in a work by M.

1 Read at the Clinical Society of London, May 11th, 1883.

Méhu a statement to the effect that when the carmine of indigo is heated with carbonate of soda, and a solution of glucose or saccharine urine, the blue color is converted gradually into green, then into red, and finally into yellow.³ Carmine of indigo is the sulph-indigotate of sodium, an intensely blue and soluble salt (solubility 1 in 120 parts water). Sulphuric acid when heated with indigo produces the soluble sulph-indigotic acid, which, after combining with a base (such as sodium, calcium, magnesium, etc.), provides us with insoluble indigo as a reagent in a perfectly dissolved state. When carbonate of soda is mixed with a solution of the carmine the latter is precipitated in a fine state of division; but when shaken this mixture may pass for a solution much like that of Fehling in color and general appearance. A perfect solution of a greenish-blue tint is, however, obtained after heating the liquid. As such it may be employed as a reliable, sensitive, stable, and non-caustic test for sugar in the urine; but on several accounts I give preference to the test papers prepared from its constituents. In their manufacture it is true that great care is required to secure throughout the filtering paper a perfectly even distribution of the sulph-indigotate; but this result has now been accomplished to my satisfaction. The papers offer the following advantages over the liquid preparation:—(a) Every paper is charged with the same definite quantity of the reagents; a uniformity is thus provided for the qualitative testing, which, moreover, becomes a standard of known value for the quantitative estimation. (b) The paper filters out a fine precipitate, so that the alkaline solution of the sulph-indigotate is perfectly transparent,⁴ and of a true blue; but, notwithstanding this fact, the color of any remnant of the reagent left on the paper is completely discharged by the sugar, so that in the quantitative estimation the colorlessness of the paper will be found the guide as to the termination of the completed reaction. (c) The portability, cleanliness, and stability of these handy tests must commend them to your favorable attention. The characteristic reaction which indicates the presence of glucose in the urine, arises shortly after the first simmer of the solution prepared from the papers, a drop or two of diabetic urine having been added before the heating. Then a beautiful violet tint suddenly spreads throughout the bright-blue solution; very quickly the violet deepens, and passes into purple; this in its turn melts into reddish-purple, which gives place to various tints of red, and these as quickly merge into orange-red and orange, and finally the solution becomes of a straw color, which remains without further change, though heated ever so long. At this point you will observe the paper of the same light-yellow color as the liquid. You will note the complete range of this striking color reaction embraces all the prismatic colors, and the order of the appearance of the successive hues is always the same. The reaction is one of great beauty; for the primary colors are not merely pure and sharply defined, but all the transitional and intermixed tints pass quickly before the eye in such rich profusion as one rarely sees in nature herself. Now, on shaking the tube the colors return in the inverse order to that in which they appeared. This remarkable

thing is not due to cooling, but to admitting the oxygen of the air into the liquid; for the varying hues at any stage of the reaction may be caught and retained for days, merely by corking the tubes full of the solution, and the return of the colors, when the test-tube is at rest, always appears first at the surface, and slowly spreads downwards, so slowly that after putting aside for some hours at least the lower half of the solution will still retain its acquired color. Experiment has shown that the tint reached in any particular observation depends on the quantity of glucose added to the test liquid—e.g., the reaction may stop at violet, purple, red, etc., and, when it thus halts, it can be easily made to proceed to the final stage by adding more of the diabetic urine, the liquid the while being kept warm. This suggests a principle on which to found a quantitative analysis. The method I propose to myself is a very simple one; it is based on the complete removal of all the colors below the pale yellow, except when the sugar exists in such small quantities as are not gaugeable by any known procedures, then the delicate scale provided by the different colors may be available.

If confirmation of the presence of sugar be further desired my series of test papers provides it. For when the mercuric chloride paper—otherwise required by one of the several methods for the quantitative determination of albumen—is dropped into the solution while still hot, after the complete development of the indigo reaction, there is produced immediately a blackish-green precipitate. No such precipitation occurs when a drop of non-saccharine urine is under examination by the indigo test, then the blue solution is merely turned into a transparent green one. Mercuric chloride, however, when added to a hot solution of mere carbonate of soda containing a drop of saccharine urine is not a test for sugar; it is only so after the full development of the indigo reaction on glucose. This final stage of the testing appears to me to clinch the presence of sugar beyond doubt.

The mode of testing is important. One of the papers should be dropped into an ordinary half-inch test tube, and as much water poured in as will just cover the upper end; a column one inch in height and half an inch in diameter will thus be produced, and the solution obtained will always acquire the same concentration. Then not more than one drop of the suspected urine is let fall into the tube from a pipette, and heat is applied. After the first change of color it is advisable to move the tube away from the flame, and merely keep its contents hot, not boiling, in the higher part of the column of heated air above the flame; then all the colors will follow in the order I have given, without disturbance from ebullition, until straw-yellow is reached, providing the amount of glucose present is sufficient to develop all the prismatic colors, if not, another drop of urine should be added. The results of the working of this test by the side of Fehling were briefly as follows:—(a) On always submitting one drop of urine to the indigo test, and the presence of sugar being shown, confirmation was invariably provided by Fehling used in the ordinary way. (b) On the other hand, whenever one drop of urine gave no reaction with the test, Fehling's solution did not give a precipitate. (c) On, however, taking more than one drop of urine a different kind of experience was opened up. Then with various urines a deep violet or purple tint would strike up on the addition of the second, third, fourth, fifth, sixth, or more drops, and Fehling employed in the usual way gave negative results. But I am inclined to think in the cases in which from two to four drops

³ L'Urine, par Dr. C. Méhu. Paris 1880.

⁴ Since coming to town I find that a perfectly clear solution cannot be obtained from the papers heated in the London drinking water, while, on the other hand, in distilled water it is as transparent as when the Harrogate drinking water was used. The larger proportion of salts in the London water, especially sodium chloride, which I know impairs the solubility of the carmine of indigo, is the probable cause of the difference. The characteristic reaction of the test is, however, precisely the same.

developed the partial reaction, that Fehling, when applied as follows, showed such a suspicious change as to almost suggest a very minute quantity of sugar; a few drops of the urine were added to a little more than the same quantity of the solution, the true blue remaining intact, and well boiled, when, though no precipitate was visible, the blue quickly turned to a decided green tint, contrasting strongly with the pure blue of the solution held by it in another test tube. I do not assert that this change of color from blue to green was a proof that sugar slightly over the normal was present, but to my mind it is suggestive, for I could not detect such a distinct color reaction with urines that, guided by the indigo test, I should class as normal in respect to sugar, or whatever is the cause of the reaction in such urines.

In all these cases there was unquestionable derangement of the liver, and in some there were decided or suspicious indications of gout, especially in those forms which are sometimes grouped under the somewhat indefinite term, "suppressed gout." They were just the cases in which it is clinically interesting to detect a little more sugar than the normal. In one case now under observation sugar has been detected at odd times during the past two years by Fehling used in the ordinary way; now, however, though Fehling gives no precipitate, but only the distinct green color just referred to, the indigo test affords a very pronounced and beautiful purplish-red reaction with the second drop of the urine. So far as I can at present decide, though I feel that further experience must be appealed to, normal urine, as a rule, gives a distinct violet tint after the addition of the fifth or sixth drop. From these observations I am inclined to believe that the indigo test provides us with an accurate and very sensitive means of detecting and gauging the normal sugar, and, furthermore, those variations which probably fill in the gap between the small quantity of sugar consistent with good health and the larger amount which characterizes ordinary diabetes. I therefore strongly suspect this test may open up an interesting field for clinical observation which has not been compassed by the reagents hitherto employed. May it not bring within our clinical vision some new facts in relation to sugar as a symptom of several disorders, perhaps especially those of the vaso-motor nervous system and the liver?

Observation likewise leads me to believe the indigo test possesses the following advantages over Fehling:—1. It will detect sugar in any proportion in the presence of albumen, blood, pus, or bile, and as readily as in ordinary diabetic urine. In the case of albuminous urine it is therefore unnecessary to precipitate the albumen and filter. It is well known when there is much albumen and little sugar—as in this urine—the latter may be overlooked by Fehling. 2. It gives no play of color with uric acid, though the latter can slowly discharge the color of the test. It is well known how this constituent in the urine breaks up Fehling. 3. Alkaline sulphides (so apt to be present in stale albuminous urine) do not, so far as I have seen, affect the indigo test applied as I have suggested. 4. The stability of the test is one of some promise, and if proved by further experience—and I know nothing to cause me to doubt it—it will be a great comfort in sugar testing. Moore's, Trommer's, and Böttger's bismuth tests are all inferior in delicacy.

The conclusions to which I am led by my observations are—(1) that the indigo test, as here presented, is a detector of glucose in the urine which possesses several points of advantage over all the old tests; (2) that it is the most sensitive of

all the reagents I have tried by the side of it; and (3) that it is less liable to fallacy than the others, even though special urines—such as albuminous, purulent, and bloody ones—are not prepared for its operation by the separation of albumen, etc. As yet I have not met with anything in the urine besides glucose which brings out the characteristic play of colors. A good qualitative test should have as one of its working properties the power to easily display the coarser variations of quantity; for these are far more useful, as a rule, to practitioners than the discovery of fine gradations, which are little more than the refinements of the laboratory. This property the test before us possesses, as you will discover after putting it on its trial, and becoming acquainted with its behavior; for, as with any new instrument, we can only discover all about it by practice. Diabetic urine for this purpose should be diluted with water—and still only one drop should be examined as before; or after the development of the complete reaction the fresh addition of a paper, or a portion of a paper may be made, when perhaps the straw-yellow will fail to appear. But each one will doubtless discover his own way to similar results. I have abstained from referring to the claims of picric acid and caustic potash, introduced by Dr. George Johnson, as compared with those of the test I here bring forward; because both—in the forms in which they are presented—are new, and their respective merits must be decided by facts and observations which can only be gathered, and trustworthily relied upon, after long and patient inquiry.

P.S.—Since reading this paper I have found that Dr. Ralfe has lately made some experiments with ordinary indigo as a test for glucose. Dr. Ralfe informs me his results were gratifying; but, desiring to use the reagent as a test paper, he found, as I had likewise done, this idea impracticable, and for the time relinquished the matter. He informed me the test, as a liquid, was used in Germany (see Neubauer and Vogel, Sydenham Society's Transactions), and about thirty years or so ago grape sugar, he believed, was employed by manufacturers to quantitatively determine samples of indigo. If so, how unwittingly one may sketch out the opposite side of the same fact, or rather may approach it from the other side; for, instead of estimating indigo by glucose, my proposition is the reverse.

FATAL CASE OF POISONING BY TERCHLORIDE OF ANTIMONY.

By R. BARRINGTON COOKE, B.A., F.L.S.,

Consulting Surgeon, Royal Northern Sea-Bathing Infirmary, Scarborough.

A FATAL case of poisoning by butter of antimony (or "butyr," as it was formerly written) is of extremely rare occurrence; indeed, the number of cases that have occurred during this century of which any record is given may be numbered upon one's fingers. The case I am about to narrate is, I believe, unique, both from the rapidity of the action of the poison after being swallowed, and from the absence of some of the post-mortem appearances usually found as the results of a corrosive fluid of this nature.

S. H—, aged forty, the wife of a farmer in this neighborhood, consulted me at various times during the past year, subsequently to which her husband took one of Lord Downe's farms at Ruston, and they removed to that village. The poison apparently travelled with them, as it appeared in evidence that it was purchased in Scarborough,

from a well-known druggist, more than a year ago, by a brother of the deceased, for the treatment of some sheep suffering from "foot-root," a common usage of this article in the North of England. I was sent for to see the deceased on the Thursday before her death (25th January last), when her mental condition was found to be unsound. It was decided to have her removed to an asylum, and great care was enjoined upon the relatives to watch her; but notwithstanding she attempted to drown herself in the "beck" the next day (Friday). The necessary steps for obtaining a second certificate were gone through, and Dr. Lowe, of Hutton Buscel, was requested to see her, which he did on Sunday, about noon. He told the coroner that her physical health appeared to be good, though her mind was unsound. After Dr. Lowe's visit at noon the family, including the deceased, her husband, her sister, and the children ate a hearty dinner of roast beef, Yorkshire pudding, and potatoes, which was not concluded before 1.30 P.M. Shortly afterwards, whilst assisting her sister to wash the dishes, etc., she vomited several times at the kitchen sink, also went to the privy in the yard, from which she walked upstairs to her bedroom, where, underneath the mattress, an empty four-ounce bottle and cork were subsequently found. The medical man who had previously seen her that morning was again summoned, and on his arrival, at 2.30, found her lying on her back, unconscious, and very livid in the face and neck. She was retching, and emitting from the mouth a frothy mucous fluid, mixed with vomit (no blood) of a brown grumous color; breathing was labored and spasmodic; pulseless; the body cold and clammy. She expired at 3.30, or about one hour and a half after the first attack of vomiting. Immediately after dinner I am informed by her sister that she went into the coal cellar, and it is presumed that she there swallowed the poison, but the precise how, when, and where remains in doubt. There can be no question that it must have been taken after the dinner, and not before. The husband swore that the deceased had never been left for one minute from her attempt to drown herself on the Friday night till her death, and the empty four-ounce bottle, with the cork beside it, were found between the mattresses of the bed upon which the woman died, and which her sister swore she had examined. From the time of getting up in the morning at 7.30 or 8 o'clock until her death the deceased was twice upstairs in her bedroom, where the bottle was found, once after breakfast (about 10) to make the beds, and again about 11.30 to shut the windows, on both occasions accompanied by her sister. The dinner hour was about 1 P.M., before which Dr. Lowe had seen her for the first time. He was summoned again at 2.30, and saw her die in less than an hour afterwards. There was no appearance on the mattress as if any of the contents of the bottle had been spilt or run on to the mattress. The bottle was labelled "Butter of Antimony, poison," and was from Mr. Eccles, Scarborough.

Jan. 30th.—*Post-mortem examination, about forty-four hours after death.*—Rigor mortis well marked. Cadaveric lividity. No marks of external violence. The cranium, thorax, and their contents were apparently free from disease. On opening the abdomen the following appearances were noted:—Great fulness of the vessels of liver, stomach, and omentum, especially of the vessels of the cardiac half of the stomach looking blackish through its mucous and peritoneal coats. Uterus healthy and unimpregnated, and an agglutinated appearance of the omentum to the subjacent parts; all other viscera appeared healthy. The stomach was then removed, both ends being tied, and a section was

made into it in the presence of the coroner, when the whole of the inner surface of the mucous membrane and subperitoneal covering was seen to be more or less intensely congested, of a dark, almost black, color. The stomach and its contents, together with some vomit, which had been secured on the day of death, and preserved by Dr. Lowe, were handed over to Inspector Dove for transmission to Mr. Fairley, the analyst for the North Riding. The larynx and trachea, down to its bifurcation, was examined. It contained a small portion of semi-fluid material, apparently vomit from the stomach, probably post mortem. False teeth were noted fitting to the upper jaw. *There was no corrugation of the tongue, or inner surface of the mucous membrane of the mouth, and no appearance of the action of a corrosive upon the lips, fauces, or mucous membrane of oesophagus.* The dress, which had been worn, was not then examined by us.

The following is Mr. Fairley's report:

"I have subjected the stomach, with adherent fluid and solid matter, to careful chemical analysis. Their total weight was about ten ounces (avoirdupois). A portion of the stomach (about two ounces) contained compounds of antimony, equal to 1.68 grain of metallic antimony, and a smaller quantity of arsenic, amounting to about 0.02 grain; so that the entire stomach contained at least eight grains of antimony and 0.1 grain of arsenic. Eight grains of antimony are equivalent to nearly forty grains of tartar emetic and to nearly fifteen grains of chloride of antimony—quantities much in excess of a fatal dose for an adult person. These compounds are the most common soluble forms of antimony. Arsenic is frequently present in compounds of antimony as an impurity, but the poisonous action in this case is mainly or actively due to antimony. The contents of the stomach have also been subjected to analysis. The same poisons were present in very large quantities, which would have been more than sufficient to cause death if directly administered. There was therefore absorbed in the tissues of the stomach a quantity of antimony much in excess of a fatal dose when taken in a soluble form; and also in the contents of the stomach a quantity of antimony which had not been absorbed into the body, but which would have been amply sufficient to cause death had it been so absorbed. The symptoms and appearances, as stated to me by Inspector Dove and by Drs. Lowe and Cooke at the post-mortem, agree with those which have been noted in previous cases of poisoning by compounds of antimony."

Christison says in "Treatise on Poisons," p. 486: "It is rarely met with as the cause of poisoning, and scarcely deserves notice here were it not that its effects differ widely from those of tartar emetic and other antimonials."¹ Taylor² has collected three cases of poisoning with it which show that it is a powerful corrosive and irritant. In two of these cases recovery took place, the dose in one being four or five drachms taken by mistake for gingerbeer, and in the other a similar quantity was taken by mistake for antimonial wine. The third case was that of a surgeon, who took intentionally between two and three fluid ounces, and died in ten hours and a half afterwards. The whole inside of the alimentary canal was black and charred from the mouth to the jejunum, and the mucous membrane seemed to have been removed along the whole of the extent of the canal,

¹ Of the preparations of antimony, emetic tartar and butter of antimony are the only salts of this metal which have corrosive properties. The former when taken in overdoses is generally rejected by the stomach.

² Manual of Medical Jurisprudence, p. 209.

and the submucous and peritoneal coats were so soft as to be easily torn with the fingers. Orfila mentions only one, and that an instance which occurred more than 200 years ago. Pereira, Trill, and Caspar mention none, Guy only those recorded by Taylor. On referring to "Neale's Medical Digest" (New Sydenham Society's latest edition), which covers a space of more than thirty years past, there is no mention of any case of poisoning by "butter of antimony." Woodman and Tidy recount the cases before alluded to, and some others, differing, however, from the Ruston case in material points. The nearest approach in point of time is one recorded in their analyses of cases, strange to say, by a namesake of mine, the late Mr. Weeden Cooke.

Peculiarities of the Ruston Case.—First, the rapid death from the time the poison is presumed to have been swallowed, at most in *less than two hours afterwards*. Secondly, the absence of charring or corrosion of the mouth, fauces, and œsophagus as compared with the post-mortem appearances of the mucous membrane of the stomach, which was dark and livid, almost black. The poison was probably swallowed immediately after the meal, and possibly the alimentary passage was in great measure protected from its action (on its way to the stomach) by the greasy food which had just been taken.

Butter of antimony is used for the treatment of foot-rot in sheep, and can be easily procured from any druggist or oil and colorman for that purpose. The now prevalent use of it among farmers for foot-rot may lead to more frequent cases of poisoning by this compound of antimony in the future, unless its sale be restricted or placed under more stringent police regulations. The evidence of the husband showed that he had no knowledge of its poisonous properties.

The Government have recently declared, through Mr. Mundella,¹ their intention to introduce "a Bill for the Amendment of the Sale of Poisons Act," which will include provisions respecting the sale of so-called patent medicines of a poisonous character. It is to be hoped that the attention of the Legislature will be called to the importance of placing some restrictions upon the sale of butter of antimony, which it appears is a highly corrosive and dangerous poison. I am not even aware that butter of antimony is scheduled under the list of articles deemed poisons, though tartar emetic, a far less powerful irritant, is so classed.

Dr. Pritchard (the poisoner) at one time lived at Hunmanby and Filey in this neighborhood, and I became acquainted with him. I have been told by an agent of one of the wholesale druggists that he was in the habit of purchasing compounds of antimony (notably tartar emetic) in large quantities, for what purpose may be inferred from the diabolical use which he made of it among the members of his own family after he had removed to Glasgow. It is within the knowledge of one medical man, at least, in this locality, that the treatment of his patients was very unsatisfactory, and their illnesses were generally of a protracted character. When a consultation was proposed the patient usually died; the inference being that tartar emetic was systematically employed for his vile purposes. I have sufficient evidence, apart from that by which he was convicted when on his trial for the murder of his wife and mother-in-law, to show that his unscrupulous use of compounds of antimony, through which he ultimately was brought to the gallows, need scarcely be matter of surprise.

My warmest acknowledgments are due to Dr. Wood (the coroner), to Mr. Fairley, and to Dr. Lowe, as well as to Dr. Thomas Stevenson, of Guy's Hospital, for the kind assistance they have rendered me in the examination and investigation of this case.

Scarborough.

ON THE IMPROPRIETY OF THE INVERSION OF PATIENTS IN APPARENT DEATH FROM CHLOROFORM, DROWNING, ETC.

By HENRY R. SILVESTER, M.D., B.A. Lond.

THE LANCET a short time ago contained an interesting article by Dr. Eben Watson, of the Glasgow Royal Infirmary, entitled "Remarks questioning the Propriety of the Inversion of Patients in the Chloroform Syncope," in which he submits on physiological grounds that this proceeding is injurious to the patient in the first place, because it has a tendency to increase the engorgement of the right side of the heart and large vessels, a condition which is known to exist as one of the most striking effects of the employment of anæsthetic agents; secondly, that this practice is useless as a means of forcing on the general circulation, for, as everyone knows, the blood must pass through the right side of the heart and through the lungs before it can be sent to the body generally; but since the heart is powerless to act on account of the difficulty which exists in the lungs, the further congestion occasioned by the inverted position of the body merely aggravates the existing evil; and, thirdly, that the venous blood in the neck and arms which gets to the brain, in consequence of the depression of the head, only deepens the coma which already exists. Now, there is no doubt that the treatment of drowned persons by inverting the body is very ancient. The attempt to restore from drowning by inverting the body is depicted on the Egyptian monuments. The exploits of Rameses the Great in Assyria are represented in the sculptures on the tomb of Osymandyos; some of the defeated enemy are carrying the corpse of their chief, who was drowned in the river Euphrates, and are in vain endeavoring to restore life by holding the head downwards to expel the water which was believed to have entered the body. It is probable that this kind of treatment continued down to comparatively modern times; for in the year 1774 the Royal Humane Society ordered that the body should not be carried on anyone's shoulders with the head hanging downwards, nor rolled upon the ground, nor over a barrel, nor lifted by the heels, and it is added that "these methods are injurious, and often destroy the small remains of life." Seeing, then, how injurious and apparently useless this method of treatment appears on physiological grounds, may it not have been revived with another object in view—namely, that by this means the heavy vapor of chloroform might be thus poured out from the lungs by gravitation? It is, however, very doubtful whether the vapor of chloroform, still less that of ether, at the temperature of the body, can be ejected from the lungs in this way, for some time since I performed a series of experiments in order to ascertain whether it would be possible to remove water (which is much heavier than the vapor of chloroform) from the lungs of drowned persons (supposing for the sake of argument that it had gained admission there) by placing the body in any of the positions which have been recommended for the attainment of this object. I injected small and large quantities of water into the lungs through the windpipe by a forcing syringe,

¹ See Hansard, Mr. Mundella, March 9th, 1883. The Bill will be introduced in the House of Lords.

and then endeavored to remove it by placing the body in various positions, such as reclining on the face, rolled from supine to prone, held up by the feet, etc., but without success, although there was less difficulty with regard to fluids in the stomach; but this is not of much consequence, as the water swallowed is usually vomited on the return of consciousness.

In the treatment of the apparently dead the following positions of the body have had their advocates—namely, resting horizontally on the face, on the side, on the back, alternately prone and supine, inverted, sitting up, bent forwards and bent backwards. Dr. E. Watson recommends the "supine and horizontal;" but experience appears to teach that the most suitable position, is that of lying on the back, the body inclining a little from the feet upwards, the shoulders and head slightly raised and supported on a firm cushion. The position is favorable for the relief of congestion of the heart and head, and both sides of the chest are free to expand, and this affords the best chance of restoration from apparent death.

Clapham Common.

ON A METHOD OF CONTROLLING HÆMORRHAGE IN AMPUTATION AT, OR EXCISION OF, THE HIP-JOINT.¹

By JORDAN LLOYD, M.B., F.R.C.S. Eng.,

Casualty Surgeon to the Queen's Hospital, Birmingham.

LET me ask my hearers after listening to this paper to judge it, not by the novelty or boldness of the proceeding which has furnished me with a subject, but by the amount of traditional uncertainty and difficulty it may tend to remove. The dread of hæmorrhage felt by a surgeon about to amputate at the hip-joint is no mere fancy. It is a matter of great importance, and the means by which the blood-loss can be safely and completely controlled are questions of supreme moment to him. It does not follow because a problem has been found difficult of solution in the past that it may not at some future time be solved in a simple manner; and it by no means follows that because the forthcoming solution is simple it is also unreliable. The present subject furnishes a case in point. All of us must remember how a few years ago, and indeed even to-day, the anxious surgeon carefully applied the gigantic horseshoe tourniquet to the abdomen of his unfortunate patient, and how gratified he was when it was ascertained that pulsation had stopped in the femoral artery; the admiration and enthusiasm of his onlookers were raised to their highest pitch; the proceeding being regarded as a marvellously skilful and wonderful surgical attainment. Under the plan I have adopted all this glory vanishes; the same end is gained by what may be considered a very commonplace procedure.

On June 17th last I performed amputation through the hip-joint on a boy, ten years old, at the Queen's Hospital, Birmingham. I then employed a method of controlling the hæmorrhage which had not, so far as I am aware, previously been used in this particular operation. The plan is, I think, simpler and safer than any of its predecessors. The amputation was practically bloodless, the hæmorrhage being as completely restrained as in operations through the lower part of the leg. The limb was removed in the manner recommended by my colleague, Mr. Furneaux Jordan. The case was one of hip-joint disease,

where excision six months previously had been followed by acute osteo-mylitis of the femur. The boy made a rapid recovery after the amputation, and left the hospital in six weeks.

The method I am about to describe contains no new principle; it is an adaptation of the well-known plan of circular elastic constriction which we owe to Professor Esmarch. The limb about to be operated upon should first be emptied of blood by elevation. This will occupy only a few minutes, and may be executed during the administration of the anæsthetic. Elevation combined with gentle friction towards the trunk renders parts as exsanguineous as the at times undesirable Esmarch's roller. A strip of black indiarubber bandage about two yards long is to be doubled and passed between the thighs, its centre lying between the tuber ischii of the side to be operated on and the anus. A common calico thigh roller must next be laid lengthways over the external iliac artery. The ends of the rubber are now to be firmly and steadily drawn in a direction upwards and outwards, one in front and one behind, to a point above the centre of the iliac crest of the same side. They must be pulled tight enough to check pulsation in the femoral artery. The front part of the band passing across the compress occludes the external iliac and runs parallel to and above Poupart's ligament. The back half of the band runs across the great sacro-sciatic notch, and, by compressing the vessels passing through it, prevents bleeding from the branches of the internal iliac artery. The ends of the bandage thus tightened must be held by the hand of an assistant placed just above the centre of the iliac crest, the back of the hand being against the surface of the patient's body. It is a good plan to pass the elastic over a slip of wood held in the palm of the hand, so as to diminish the pain attending the prolonged pressure of the rubber bandage. In this way an elastic tourniquet is made to encircle one of the innominate bones; checking the whole blood-supply to the lower extremity. The elastic bandage may be secured above the iliac crest in the usual manner with tapes, and may be prevented from slipping downwards by being held with a common roller tied securely over the opposite shoulder. Experience has shown, however, that no mechanical means answer so well as the hand of a trusty assistant. When the band is once properly adjusted, the assistant has only to take care that it does not slip away from the compress or over the tuber ischii. The former is prevented by securing pad and tourniquet together with a stout safety pin; and the latter by keeping the securing hand well above the iliac crest, or even more safely by looping a tape beneath the elastic near the tuber ischii, passing it behind under the sacrum and having it held in that position. The solid rubber tourniquet may be used instead of this bandage. I prefer, however, the bandage. The soft parts are less damaged by reason of its greater breadth and it is less likely to roll off the compress placed over the external iliac.

The ligature, being altogether above the limb, is out of the way of the surgeon in any operation at or about the hip-joint. The great trochanter is fully exposed; the hip being free upwards as far as the iliac crest and inwards to the perineum. The plan is equally applicable in amputation by transfixion or in excision of the joint, as in the case above alluded to. All previous operators have controlled the blood flow during hip amputations by an apparatus adapted in some manner to the abdomen, except in the case of the ingenious rectal lever recently introduced to the profession by Davy. Esmarch himself says in his *Surgeon's*

¹ A paper read before the Midland Medical Society, March 21st, 1883.

Handbook "aortic pressure must be employed for disarticulation and excision of the hip." He recommends either Pancoast's or his own abdominal tourniquet; both instruments being similar in principle. He describes several methods of compressing the aorta by a circular elastic bandage applied round the loins, and of these Brande's is undoubtedly the best. The latest and probably a better procedure than any of the above is Davy's plan of compressing the common iliac artery by means of a wooden lever introduced into the rectum. The following advantages are claimed for it by its inventor over all apparatus which acts upon the aorta through the abdominal parietes:—

1. There is less disturbance of the general circulation, as that of the affected limb only is interfered with.
2. There is no interference with abdominal respiration; a very important gain in patients under anæsthetics.
3. There is less danger of injuring the abdominal contents.
4. Less pressure is required to control the blood stream through the common iliac artery than through the aorta.
5. The instrument is less likely to get displaced.
6. It is more rapidly and easily manipulated.
7. It is cheaper and more durable.

All these advantages hold good in the case of Esmarch's bandage as I apply it, most of them in a greater degree than when the lever is used. The bandage has, however, the following additional claims over the lever:—1. The simplicity and certainty of its application; no previous experience being necessary to compress the vessels there is no possibility of going wrong. 2. The security with which the vessels are controlled, regardless of the movements of the patient or manipulations of the operator. 3. The freedom from danger of injury to the rectum or abdominal contents. (Davy related a case at a recent meeting of the London Clinical Society, in which he himself had wounded the rectum with his lever; the patient dying on the following day of peritonitis.) 4. Its applicability to cases in which the rectal lever could not be employed, as in strictures of the bowel, intra-pelvic growths, and arterial abnormalities. 5. It requires no special apparatus.

I have adopted the method in a case where I stretched the sciatic nerve; the operation, being bloodless, became extremely easy. I have used it with similar advantage in investigating an obscure case attended by the presence of chronic sinuses about the great trochanter; caries of the outer surface of the innominate bone was detected as the cause. I have applied it in a recent case of excision of the hip. Venous hæmorrhage of a trifling amount occurred in this case; it proceeded, however, from the tissues below the ligature, and was due to the limb being imperfectly emptied of blood before the band was adjusted.

My colleague, Mr. Bennett May, kindly gave me an opportunity of employing the method in a case of amputation at the hip-joint on Dec. 17th. The patient was five years old, and was suffering from acute osteo-mylitis of the upper end of the femur. Disease had extended to the joint, and was threatening death by the foulness and profusion of the discharge. The limb was thoroughly emptied of blood by elevation and friction. A double layer of Esmarch's bandage was used in the manner above described. About two drachms of blood escaped from the posterior flap only. The band was in position for nearly fifteen minutes, all visible vessels being secured before relaxing it. There was no arterial spurt throughout the operation. The child, already in a desperate condition before amputation was performed, died from shock about ten hours afterwards.

By the kindness of my friend Mr. Spofforth, of Kidderminster, I was afforded an opportunity of

trying the plan at the Kidderminster Infirmary on Oct. 8th. The case was one of amputation at the right hip-joint for morbus coxæ. The patient was a man twenty years of age. After Esmarch's bandage had been rolled from toes to groin I applied the elastic in the manner above described. The hip-joint was first explored through a 5-in. incision made above and behind the trochanter, with a view of performing excision if the state of the bones would allow of it. Affairs were so bad, however, that Mr. Spofforth at once proceeded to amputate by Furneaux Jordan's method. The time occupied from the first incision to the ligature of the last vessel was twenty minutes, and the amount of blood lost was about three ounces. This loss, greater than I had previously seen, came entirely from the hinder part of the exploratory incision, and was due to the posterior half of the bandage being insufficiently tight. This was readily remedied by firmer traction, and the bleeding completely restrained. The patient made a rapid recovery, and left the infirmary in five or six weeks. This patient, being a well-built adult, I was led to use the elastic band in three folds instead of two, thinking, perhaps, that the latter would not exert sufficient pressure. It is quite unnecessary, however, to use more than two layers to control any bleeding efficiently; a greater number has the disadvantage of acting extremely painfully upon the hand which is holding them. The circulation throughout the largest vessels may be controlled by slighter pressure than is generally adopted. Esmarch's bandage and tourniquet are, as a rule, put on unnecessarily tightly. Arterial walls are soft elastic tubes, and a very moderate pressure is sufficient to check the current through them.

I submit this method to the profession feeling every confidence in its reliability, having applied it in seven operations—viz., three amputations at the hip-joint, one excision, one nerve-stretching, and one exploratory. Some of these cases were in the practice of my friends; it has pleased them equally with myself.

P.S.—Since writing the above I have had a fourth case of amputation at the hip-joint in a girl aged twelve years. The operation was performed on April 7th. Scarcely any blood was lost, and she is now nearly convalescent.

A CASE OF TUBERCULAR PERICARDITIS.

By W. JULIUS MICKLE, M.D.,

Medical Superintendent of Grove Hall Asylum, London.

On account of the rarity of tubercular pericarditis, the particulars of a case not long ago under my care may possess some interest. My remarks refer more especially to the pathological aspect of the subject. *THE LANCET*, in one of its leading articles, has dealt with a few of the points involved.

By some it has been held that in pericarditis with tubercle the tubercles were the result of the inflammation, and were situated in the inflammatory false membranes. On the other hand, Sir G. Burrows long ago maintained that the tubercles were the cause of the inflammation, and were primarily situated in or under the serous layers of the pericardial sac. Cases actually observed appear to show that the affection may be tubercular from the onset; and, on the contrary, in other cases, that what was originally a simple pericarditis may subsequently become associated with tubercular growth. Nevertheless, it is not unlikely that the former of these is the usual condition in order of time. Cases are on record of tuberculosis of the pericardium, as well as others of tubercu-

losis of the heart muscle, without inflammation; and the possibility of the existence of pericardial tuberculosis before any pericarditis has made its appearance is also confirmed by examples of acute miliary tuberculosis of the pericardium in cases of acute miliary tuberculosis more or less generalized in character, and affecting the serous membranes more particularly. The tubercles in tubercular pericarditis have been written of by some as if always found in the false membranes, as well as in the pericardial layers themselves. This, however, is not a universal rule; in some examples no tubercles exist in the false membrane, while they are well marked in the layers of the serous membrane itself, as in the case by Dr. T. B. Peacock. It seems probable that tubercles most frequently form at first in or beneath the pericardium, especially its visceral layer, and occasionally associated with these are tubercles in the muscular substance of the heart itself. There are indubitable examples of this on record. May not the miliary granulations of the pericardium in some of these cases have been secondary to the caseous masses in the heart muscle? Then, again, with reference to some of the cases of so-called tubercle of the heart, reported now a long time ago, the suggestion will intrude itself that the masses described as tubercular were perhaps syphilitic nodules in reality. The true tubercles, however, sometimes attain considerable size, as in a case reported by Dr. Bristowe. Although rare in those who have no tubercle elsewhere, tubercle of the heart or pericardium is not exclusively limited to cases with tubercle in other parts, as has been erroneously asserted. Thus in one of Dr. Peacock's cases no tubercle was found in any other organ, and in another none was found save in the bronchial glands. Other observers have reported a few similar facts. Tubercle being thus occasionally found nowhere except in the heart or pericardium and bronchial and mediastinal glands, Cruveilhier held that in some examples of this kind tubercle of the heart was probably primary, and the affection of the bronchial or mediastinal glands secondary thereto. This view has been opposed on what, with due deference, I think to be inadequate grounds. By Bauer tubercular pericarditis is said to be accompanied with more or less abundant exudation into the pericardial cavity, referring apparently to liquid exudation; yet Dr. Vailard, whose case was summarized in *THE LANCET* and accompanied with some general observations, speaks of the pericarditis as being dry in the large majority of cases. More knowledge is also desirable as to the few examples of undoubted liquid effusion, inasmuch as one observer makes it a diagnostic element in examples of tubercular pericarditis of this kind that the effusion is not of very large amount, whereas, on the contrary, in the view of others, an abundant effusion, by its very abundance, favors a conclusion as to a tubercular origin of the pericarditis.

In the case I will mention the age was greater than that more usual to patients with tubercular pericarditis, the great majority of these being under the age of forty, although examples have been observed even in somewhat advanced life. The patient, D. P., an old soldier, died at the age of fifty-four, mainly of bronchitis, after having been for many years insane, hemiplegic, and aphasic. Death was preceded by occasional vomiting, a general convulsion, and coma. The seats of tubercle were the pericardium and the pericarditic pseudo-membranes, the right lung, and very slightly, especially on the right side, the bronchial glands. The first-named of these parts suffered the most severely; for the layers of the pericar-

dium were universally and closely conjoined, and adherent by thick intervening dry false membranes, and both of the serous layers, but especially the neo-membranous formation, were thickly strewn with numerous embedded tubercular nodules of dirty-whitish hue. The cardiac valves were healthy; the left coronary artery was highly atheromatous, the right slightly so, the aorta net. The left ventricle was contracted and empty; the other cardiac chambers were gorged with dark fluid blood. The weight of the heart, with pericardium, was 10½ oz. In the left lung was general bronchitis, and it was entirely covered by old close pleuritic adhesions, and posteriorly by old inflammatory thickening of the visceral pleura. The right lung exhibited adhesions posteriorly, and patches of pleuritic thickening capping the apex, and situated over the lower part of the posterior and the middle part of the external surface. At the summit were minute greyish subpleural granulations, at the inner side of the apex a partly putty-like, partly cretaceous nodule, surrounded by dark cicatricial fibroid growth, and in the pulmonary tissue a few small nodules or granulations. Some bronchitis and pulmonary congestion were noted. The other lesions need not be described in detail, as they have been published elsewhere, with a clinical history of the case, particularly with reference to aphasia. Briefly, the other changes were large destructive lesion of some convolutions of the left cerebral hemisphere and of the adjacent white substance, and a similar, but much smaller, lesion in the right cerebral hemisphere, to which were added secondary cortical atrophy, and secondary descending degeneration and atrophy coursing through the left crus, pons, medulla oblongata, and the right post-lateral columns of the spinal cord, the antero-internal part of the left anterior column being also atrophied. Finally, the kidneys were slightly granular and cyst-containing.

Since writing the above I have made a necropsy in the case of J. C., of the 5th Brigade Royal Artillery, for several years suffering from chronic mania, and who died at the age of thirty-one. After admission the heart's apex beat was two inches and a half below, and half an inch within, the left nipple. Slight signs of pulmonary phthisis were followed four months before death by sinistral pleurisy with gradually accumulating fluid effusion, finally causing dyspnoea and cardiac displacement. Owing to the terror and plunging about of the patient the chest was aspirated with most extreme difficulty; and eighty-four ounces of clear sero-fibrinous fluid were removed with very great relief to the symptoms. Only very partial reaccumulation took place, and the patient's alarm now made re-aspiration impossible. The pulmonary signs became more marked; death by gradual asthenia. There were firm old general pericarditic adhesions, the false membranes being vascular and organized. Scattered here and there over the whole surface of the heart were flattened, firm, whitish plates, of fibro-caseous appearance; with some of these both the false membranes and the visceral pericardium separated; with others only the false membranes. Besides these, there were some transparent miliary granulations on both the visceral and parietal layers of the pericardium, but apparently limited to the neo-membranes and not embedded in the pericardial layers themselves. Five ounces and a half of fluid in the left pleural cavity; thick fibrinous deposits on both pleural layers; some pleural granulations. Small cavities, tubercular granulations and clusters in both lungs. Caseous bronchial and mediastinal glands, one of the latter, impinging on the left sternal edge, being

much softened. Caseous lumbar and mesenteric glands; some tubercular ulcers of small intestine.

ON THREE SUCCESSFUL CASES OF NEPHRECTOMY;

WITH REMARKS ON THIS OPERATION.¹

By J. KNOWSLEY THORNTON, M.B., C.M.,

Surgeon to the Samaritan Hospital.

AMONG the recent advances in surgery the operations on the kidney hold a foremost place. For some of these operations the lumbar section is alone suitable; but for the most serious of all, nephrectomy, it is still an open question which is the best incision. Carefully recorded cases and results will in time settle this important matter, and I offer the record of these three cases with the certainty that they will be found interesting. The first has already been published in *THE LANCET* (1880), but it will be useful to recall its leading features.

CASE 1.—The patient was a delicate undersized child of seven, and had been known to have some swelling of the abdomen since she was two years old, and probably it had been there from birth. I was requested to see her by Dr. Day, when, having diagnosed renal tumour, I suggested an antiseptic aspiration to make sure as to its nature and contents. This operation I performed, and removed six pints and a half of rather dark and slightly cloudy urine. In two months the tumour had refilled, and I removed the left kidney, making the incision in the median line to the left of the umbilicus. The operation was a long and difficult one, the enucleation requiring great care, as the tissues were very delicate and contained many large vessels. The child also took the bichloride of methylene badly, straining and retching. The renal artery and vein were tied separately, and then by a third ligature round the whole pedicle. There was no distinct ureter, merely a thin fibrous cord where it should have been. There was much exposure of the intestines and peritoneum generally to the spray and sponges, and the former got into the way and increased the difficulty of the operation. The patient was very sick and restless during the first twenty-four hours, and the temperature ran up to 101·6°; pulse 150; respiration 32. The urine was scanty and then bloody for about the same period. Then the pulse and temperature steadily fell, and normal urine was freely secreted. The bowels acted on the fourth day; the sutures were removed and the wound entirely healed by first intention on the sixth day; and the patient was running about the ward on the fourteenth day. Last year I showed her to the members of the International Congress—a fine, strong, healthy child, and no longer small for her age.

The points I would call special attention to here are the difficulty caused by the intestines getting in the way, and the general exposure of the peritoneum to the spray, sponges, blood, etc.; the simplification and diminished danger caused by the impervious condition of the ureter.

CASE 2.—M. D—, aged twenty-six, married two years and mother of two children, was placed under my care by my colleague Dr. Prickett, at the Samaritan Hospital, in February, 1882. She was hectic, emaciated, and in great suffering. Miscarriage of a six months' foetus occurred a year after marriage; a boy was born in September, 1880, and

a girl on Nov. 4th, 1881. The first was a natural labour, and the health was good till she became again pregnant, when pain in the right loin began. The urine during the whole period of gestation was thick, and had a slimy deposit. The labour was a long one, and was followed by a sharp flooding. On the eleventh day inflammation in the right iliac fossa set in, and seven or eight days later the left leg became painful and was very much swollen. She was in bed for six weeks. She never lost the pain in the right side, and latterly had noticed a swelling there. The pain was at times spasmodic, and very severe, shooting down the course of the ureter towards the right thigh. On examination I found a fluctuant tumour of considerable size in the right loin, with the colon curving round its inner border. The urine was loaded with pus, ammoniacal, and offensive. Pulse small and quick, tongue and breath foul, hectic flush on cheeks, no appetite, frequent vomiting, and high fever in the afternoon and evening.

As it seemed impossible to decide whether the case was one of scrofulous pyonephrosis or calculous pyelitis, I determined to cut down upon the kidney through the loin, and explore it. The operation was performed with full Listerian precautions on Feb. 4th. There was considerable hæmorrhage from the tissues cut through, and from the kidney when cut into, and the points that struck me, as in the two other nephrotomies which I have performed, were: first, the much greater amount of hæmorrhage, as compared with the abdominal section; second, the very imperfect knowledge to be obtained as to the condition of the kidney. I could find no stone, and nothing to account for the condition—merely a sacculated kidney with very offensive pus. I accordingly introduced two large red-rubber drainage-tubes, sewed up the greater part of the incision, passing two of the sutures through the upper and lower angles of the incision in the kidney, and dressed with the usual gauze dressing. I did not think that the offensive odor of the pus necessarily implied sepsis (for reasons which it would take too long to enter upon here), and I therefore used a very large gauze dressing, as I knew from previous cases that the discharge would at first be very great, and I was specially anxious, both for the present safety of the patient and for the future of the case, to make it aseptic if possible. The temperature rose within a few hours of the operation to 104·6°, and the pulse, which was very feeble, to 108; the first urine from the bladder was loaded with pus, the second still contained some, and the third was clear and normal. The temperature remained high for the first three days, and the patient was very weak and ill, though she took fluid nourishment well after the first thirty-six hours. On the second day after the operation the bladder urine was free from albumen. The operation had then demonstrated the healthy condition of the other kidney. The urine soon showed signs of carbolism, and on the fifth I changed to eucalyptus gauze. The result was satisfactory so far as the state of the urine went; but in a very short time putridity became manifest, and pus, which had soaked through sixteen layers of the gauze, teemed with all kinds of bacteria. I am not at all sure that it was ever an aseptic case; indeed, I think the temperature and general condition of the patient are against the supposition, but it was not until after the use of the eucalyptus that I became absolutely certain. Ultimately the wound healed fairly well, the sutures were removed, first one tube and then another withdrawn, and for a time the patient improved greatly, and there seemed less pus from the opening. The evening temperature remained, however, about

¹ Read before the Medical Society of London Nov. 13th, 1882.

100°, and in three weeks pain in the course of the ureter, which had never entirely ceased, increased again. The evening temperature began to run up, and the morning temperature was rarely under 99·4°; appetite failed, and there was fresh pain over the surface of the kidney. I therefore decided to remove the kidney by abdominal section, making the incision along the outer border of the rectus abdominis, as recommended by Langenbück, of Berlin, in the discussion on nephrectomy at the International Congress. I also decided to use the loin opening for drainage, as I could hardly hope to remove the kidney without fouling the wound to some extent with the septic matters escaping freely at the loin opening.

The operation was performed on March 11th, 1882, with the usual Listerian precautions. In order to destroy the exciting sepsis as far as possible, I commenced by passing a catheter into the kidney through the sinus, and flooding it out with a large quantity of iodized water. I then made a six-inch incision along the outer border of the right rectus abdominis, and found that the hæmorrhage from the parietes in this situation was even less than in the usual median incision. The peritoneum was easily recognized and opened without seeing omentum or intestines, and the kidney at once exposed. I scratched a hole through the peritoneal covering, and enucleated down to the vessels with but trifling hæmorrhage; I tied them as in the first case, separately, and then with a third ligature round the whole pedicle. The ligatures were nearly an inch from the aorta, and yet left a sufficient distal stump after division of the pedicle. The remainder of the organ was enucleated with difficulty, especially round the loin opening, and up towards the liver, where I was obliged to leave a portion of capsule, in which a large artery spouted, and was secured with difficulty. Several vessels in fat and capsule were tied, in all cases with fine carbolized silk with the ends cut short. As soon as the kidney was free I drew it up, and seizing the ureter in two places near the kidney, with strong Wells forceps, divided it between them, immediately cleansing the bladder end with an iodized sponge and then tying it, had it held outside the wound. Immediately the kidney was removed, I passed a sponge soaked in tincture of iodine from above down and out through the loin opening. As there was a good deal of oozing among the loin muscles which the iodine failed to check, I applied perchloride of iron. I then passed a red-rubber drainage-tube from the lower angle of the abdominal incision across the wound, and out at the loin. The incision was closed up to the tube with the usual carbolized silk sutures, and the end of the ureter was brought outside and fastened by a pin. I believe this is the first case in which the ureter has been so treated, and I think it is of great importance. In most cases the ureter is dilated and diseased (it was very markedly so in this case), and contains putrid material, and if its bladder end be tied and dropped into the wound, it must be a dangerous source of sepsis. The kidney after removal weighed 1 lb. 2½ oz. The temperature the night before the loin nephrotomy was 101·6°, and the evening after operation 104·6°; it was high for many days, and only once or twice touched 98·4° in a morning up to the falling back before the nephrectomy. The night before the nephrectomy it was 102°, and the evening of the operation was 101·4°, but only the second day it fell in the afternoon to normal and never rose again above 99·2°. In the first operation the loin wound was bathed with the kidney contents, while in the second it was rendered thoroughly aseptic by the precautions taken, as its after-progress proved. There

were eighteen ounces of good urine in the first twenty-eight hours after operation, and thirty-eight ounces in the next thirty hours. After this she was able to pass her own urine, and the quantity varied from fifteen ounces to a pint daily. Both wounds remained aseptic, and there was but little sero-sanguinolent discharge from the loin opening. The drainage-tube was removed through the upper opening on the fifth day. The sutures were removed on the seventh and ninth days. The bowels acted naturally on the tenth day. Both wounds healed completely on the same day, the eighteenth, after operation, and she went home well on the thirtieth day. I should have mentioned that the urine during the first twenty-four hours after operation was slightly green and contained one-tenth of albumen. Later there was at times some coloring of the urine, and, as she had after the first operation shown symptoms of carbolism, I dressed with boracic lint as soon as I thought it safe to leave off thorough Listerism. When she left the hospital she was passing daily from a pint to a pint and a half of healthy urine.

The special points to which I would direct attention in this case are—1. The temporary benefit and after failure of the nephrotomy. 2. The greater difficulty of operation and smaller command of the kidney in the loin incision, as compared with the lateral abdominal one. 3. The smaller amount of constitutional disturbance attending the latter operation. 4. The fact that even with the septic condition pre-existent, it was yet possible by care and the free use of tincture of iodine to have aseptic wounds. 5. The method of dealing with the ureter.

The kidney was found after removal to contain a large number of small dark calculi, consisting of pus, epithelium, oxalate of lime crystals, and blood, the latter forming a cake over their exterior. It seems not improbable that they were formed after the nephrotomy, and that the original opinion that the case was one of scrofulous pyonephrosis was correct.

CASE 3.—M. P.—, aged fifty-eight, widow, an enormously fat woman, with much color and a feeble circulation, was transferred to my care at the Samaritan by Mrs. Atkins, of the New Hospital for Women. The amount of adipose tissue rendered examination very difficult, but the presence of a large fluctuant tumour could be distinctly made out in the right side of the abdomen, and the colon could be traced along its inner (left) border, and also a small clear area between its upper margin and the liver. Increasing size was noticed sixteen years ago, with loss of appetite, sickness, and "matter" in the urine. She was in the Women's Hospital, Soho-square, and Dr. Protheroe Smith told her that she had a tumour of the right kidney. This illness began with a sudden discharge of pus in the urine, after sickness and pain in the loin. For some years periodical attacks of diarrhoea gave her relief. In November, 1879, the tumour was very large, and she went into the New Hospital for Women, where it was aspirated, and a quart of very thick pus removed. Aspiration was repeated on March 6th, 1881, January 19th, 1882, and in February, 1882, when sixteen, eight, and three pints of pus were withdrawn. When I first saw her she was suffering much from chronic bronchitis, and the cough was still troublesome at the time of operation. She had a fair pulse (92) and an evening temperature nearly two degrees higher than the morning one. The urine was pale and thick, with muco-pus, sp. gr. 1015, and slightly acid. Though the patient was not a very favorable subject for nephrectomy, encouraged by the increased facility af-

forded by Langenbück's incision, and knowing that aspiration was ceasing to afford even temporary relief, I determined, with her full consent, to attempt the operation.

I operated on March 15th, 1882, commencing, as in Case 2, with a 6-in. incision to the outer side of the right rectus abdominis, and reached the kidney with little trouble or hæmorrhage. Finding the peritoneal capsule mobile over the kidney I enucleated a small space, tapped the kidney, and removed twenty pints of pus, taking great care that none was spilt over the wound or peritoneal surfaces. I closed the puncture by a plug of iodized cotton-wool before proceeding with the enucleation, as in the course of it the successive aspiration punctures were found surrounded by a deposit of caseous lymph, each was freely scrubbed with tincture of iodine. The renal vessels were reached with difficulty, my arm being up to the elbow in the abdomen. I found it impossible to distinguish the vessels and tie them separately, I therefore scratched a passage round them with my finger, and so passed a ligature. I cut the kidney away, securing the openings of the vessels in the kidney by a pin and twisted suture, as I had learnt from Case 2 that the hæmorrhage from this source might be very serious. The kidney was then enucleated from its capsule; an immense number of fine silk ligatures were used, and a horrible-looking mass of torn capsule and fat returned into the loin, when the enucleation was complete. I treated the ureter as in Case 2. Fearing that some fluid might accumulate in the large capsule remaining, I put in a short glass tube, and brought it out through the centre of the wound. This proved quite unnecessary; and nothing coming from it, I removed it on the second day. After all the sutures were fastened, a sponge was missing, and I had to remove some to search for it. I found it in the bottom of the capsule. This accident, and the exhaustion and refilling of the spray, prolonged the operation, which lasted three hours. The sac, after removal, weighed four pounds seven ounces, and consisted of two large chambers, with a round opening between them. The cause of all the mischief was a small umbrella-shaped stone, its point being firmly wedged into the mouth of the ureter.

The patient had been passing about a pint and a half of urine in the twenty-four hours before the operation, and in the first twenty-four hours after it nineteen ounces were drawn off, the last specimen being of a clear amber color, with light mucous cloud, and free from albumen. The temperature in the night before the operation was 101.4° and the pulse 84; after the operation the highest temperature was 100.4° and the quickest pulse 104. The sole complication was a sharp attack of bronchitis on the second and third days. The treatment consisted of digitalis in the beef-tea injections, chlorate of potash, citrate of potash, and, later, carbonate of ammonia by the mouth, with poultices to the chest. On the third day the temperature was 98.6°; pulse 96; and the urine free and loaded with urates. On the seventh day the bowels acted freely and naturally. On the ninth day putrefaction had spread from the end of the ureter, and the surface of the wound was red and irritable; it had healed by first intention, and all the sutures were removed. On the fourteenth day the wound round the ureter gaped a little, and, in spite of red lotion and various stimulating applications, did not heal. Recognizing the fact of her long residence in hospitals, I advised her to go home, and there, under the kind care of my friend, Dr. Basil Morison, of Canonbury, whose patient she had previously been, the wound healed rapidly. She went home thirty-four days

after operation, and a month later I saw her strong and well.

The special points in this case are—1. The long-standing disease and frequent aspirations, leading to the expectation of serious adhesions. 2. The age of the patient, and bad general health. 3. The prolonged operation, due to the difficulties arising from the fatness of the patient, extensive adhesions, and accidents already referred to. 4. The perfect and rapid recovery without fever.

The three cases taken together seem to me to demonstrate the advantage of the lateral over the median incision. The perfect suitability of the abdominal operation to all cases in which nephrectomy, and not mere nephrotomy, is the end aimed at; the capability of the peritoneum to dispose of large quantities of effused fluid under aseptic conditions, without the aid of the drainage-tube, and without serious constitutional disturbance arising from the absorption of the effused fluids, even after the removal of such an important eliminator as the kidney. The great differences in the ages of the patients, seven, twenty-six, and fifty-eight, and the varying diseases for which the operations were performed, make the records of especial value. The operation of Langenbück with the extra-peritoneal treatment of the bladder end of the ureter, seems so surgically perfect that I cannot conceive any case presenting itself in which I should care in the future to face the difficulties and uncertainties of the loin incision. Indeed I should be inclined to recommend an exploratory incision by the lateral abdominal section, with careful Listerian precautions, in any case in which it was of importance to thoroughly examine the kidney and ureter.

I think there can be little doubt that the impaction of some of the minute calculi found after the second operation in the kidney in Case 2 originated the disease, and the last two cases thus illustrate how small a stone may set up mischief which ends in the destruction of the kidney. A loin nephrotomy or nephro-lithotomy would probably have failed in either, as it would have been impossible to reach the stone in Case 3, and some of the minute stones would have been sure to escape detection in Case 2, as they were scattered through the sacculi, and not all in one place. I failed to detect any of them when exploring the kidney at the first operation.

SCARLATINA EVOLVED FROM DIPHTHERIA.

By JOHN MEREDITH, M.D.

THE question of evolution of scarlet fever from a correlative morbid condition appears as yet in the air rather than among the accepted tenets of the profession. Still the probability of such a development is being asserted, particularly from a diphtheritic condition. That there is a great intermixing of scarlet fever and diphtheria in certain localities is apparent to all readers of sanitary officers' reports, and it is also acknowledged that there is frequently met with an inflamed condition of the throat having decided characteristics of neither, yet showing undoubted resemblance to each of them. The explanation of the unusual prevalence of these during a great part of last year and the commencement of this is sought in meteorological conditions—for example, the excessive moisture and rain lately experienced. Meteorological conditions, taken in their widest sense, are equivalent to changes of latitude and isothermal areas. It is this, the climatic condition, that influences, not necessarily the part of the earth dwelt upon. When therefore climatic conditions

prevail at a place different from the conditions usually prevailing at it, this difference must of necessity influence every biological state, and life course has to adapt itself to altered and altering circumstances. In general these alterations are all but imperceptible, if not altogether so, as far as our capacity for perceiving goes; but occasionally it is otherwise, a tangible variety is evolved, which we, seeing only a portion of the course of action, put down as an exception; or it may be in regard to disease as sporadic. This, I take it, is the state of things through which evolution operates. Thus, some of the ordinary continued fevers of this country perplexed not a few of our profession when they had first to deal with them in tropical countries, and this may be said of other diseases besides continued fevers. Any of those perplexed observers would have had no difficulty in recognizing the true character of the fever or other disease if he met with it in the country where he first learnt to diagnose it. It has been more the habit to study disease as an entity with firmly fixed specific characters than as a mode of motion always showing variations, and these differing according to the character of the subject and the surroundings thereof.

A paper full of interest, and exceptionally suggestive, was read by Mr. K. W. Millican before the British Medical Association at Worcester last August, and afterwards published, on "The Etiology of Acute Specific Diseases." In this paper Mr. Millican brings forward certain facts relative to diphtheria and scarlet fever, and argues that the one disease may, and at times does, give rise to the other. Before the appearance of Mr. Millican's paper I had had occasion to think that the morbid condition which we recognize as diphtheritic sore-throat was capable of inducing by infection in another a scarlatinal disorder, and this in its turn, in a third person, a case of pure typical scarlet fever. The circumstances which led me to form this opinion were the following. Towards the end of June, 1882, cases of illness of undoubted diphtheritic character occurred in this district (Wellington, Somerset). There was no case of scarlet fever, nor had there been one for many months. Some of the earlier cases of diphtheria passed by—ending in recovery without coming under medical observation. To this variety belonged the case of a housemaid in a family which I have to refer to. This girl went out for an afternoon one day towards the end of June; where she went to I did not learn until some months afterwards, when it transpired that she went to see her father living a few miles from her place of service, and in the country. He was suffering at the time from a severe sore-throat, but the specific nature of it I am not able to state, as the man was not attended by any medical practitioner. The girl, a few days afterwards, was noticed to be looking ill; sallow, with a peculiar facial expression, or, perhaps, absence of expression; did not take her food as usual. She made no complaints, and did not give up her work; and before long recovered; before this came about her fellow servant, the cook, was noticed to be ill, complaining of sore-throat, and when examined this was found to be due to several diphtheritic patches on the tonsils. She complained of great languor, severe headache, a gush of perspirations at times, and a peculiar physiognomic appearance. She was treated with tincture of iron, nitric acid, and chlorate of potash gargles. The diphtheritic exudations soon disappeared, and recovery followed in due course. The two servants occupied the same bed. In the house there were three children, whose ages were eight, seven and six, and their intercourse with the cook was pretty constant usually, but this was stopped as soon as

the character of her illness was discovered. However, on the 1st of July, the eldest, a girl, was not well. She complained of headache, and was sick several times. At first this was put down to her having eaten some unripe fruit in the garden. The child was also hot and feverish. The throat when examined showed no diphtheritic exudations, but it had a peculiar florid appearance such as I have since often seen in cases of diphtheritic character. The cook had a similar appearance when examined some days before, but she had no skin rash. The child soon showed this, although at first it did not appear particularly characteristic, and I was more inclined to ascribe it to gastric irritation than anything specific. Another day's observation clearly showed that the case was one of scarlet fever; the rash was well out over most of the body and the case progressed favorably but not without showing some peculiarities, particularly in regard to the secretions of the kidneys. She often complained piteously of pain in the back in the region of the kidneys. The urine was frequently examined both by Mr. Kidgell, who kindly attended the case with me, and by myself, but without discovering any albumen, at all events nothing beyond a faint trace. It gave an alkaline reaction, the specific gravity was low, and there was frequent desire to pass it, and the passing was attended with some irritation and pain. There was, as mentioned, considerable gastric irritation; for several days nearly everything taken was rejected. After a time signs of improvement were observed, general desquamation followed, and the little patient made a good recovery eventually.

On July 2nd the youngest child, a girl aged six, complained of being ill. Her head and right ear ached. She was sick and very feverish. Her throat was red, with no diphtheritic patches. Her condition in most respects was similar to that of her sister, only the scarlatinal rash was much more general and the body temperature higher. An abscess formed in her ear, and discharged, and continued doing so for weeks. The other symptoms were milder in this than in the first case, yet there appeared to be something unusual about it.

On the 6th the third child, a boy aged seven, was seen to be ailing, complaining of headache. He had been isolated from his sisters for five or six days. This course was taken as soon as the nature of their illness was suspected to be anything specific. It was not his habit to be as much with the cook as his sisters, consequently it may justly be inferred that he derived his illness from one or other of them, and not from the servant. He complained of sore-throat, but not very much, and in due course the scarlatinal rash came out well all over his body in quite a typical character, differing a little in this respect from his sisters' cases. He had no complications, and his illness proved an exceptionally mild one, and was succeeded by free desquamation. At the time he was taken ill his mother sickened, her sickness beginning with a rigor, and a feeling of aching discomfort. She felt chilly, sick, and prostrate. The temperature of the body rose some two or three degrees above normal, and remained so for several days. Her head ached, and she had a heavy expression of countenance. Free perspirations set in at intervals, which were followed by a feeling of exhaustion, and continued for several days. The throat had a reddish blush, nothing else. There was no rash over the body, nor any subsequent desquamation. The illness appeared to me to have been diphtheria without the characteristic tonsil exudations that are usually looked for. The patient had had scarlet fever in early life.

As I have already to some extent stated, I made

every inquiry I possibly could in order to ascertain if there had been any communication between these scarlet fever cases and previous ones elsewhere, and the result was that I could not find any clue implying contact either directly or indirectly. Such, in brief, is an outline of my thesis. My object has been to note leading features rather than close details, and I have formed the opinion that the scarlatinal disorder was an evolved one—a correlative outcome, and not the immediate result, of contact, on the following among other grounds:

1. There was no reason to infer contact with scarlet fever, but there was with diphtheria.

2. The accession of the illness in the case of the eldest child was in some respects unusual, taking the symptoms as a whole; the great irritability of the stomach, with the headache and the way the rash appeared, presented marked difference from those of the boy who was taken ill a week later.

3. The behavior of the urinary secretion—its alkaline reaction, low specific gravity, frequent desire to void it, and the passing being accompanied with pain and discomfort. There was no albumen nor any sign of dropsy; but there was, I may add, a little arthritic swelling and pain at the wrists and in one ankle, lasting for a few days. Now, I have again and again met with persons suffering from such symptoms as these during diphtheritic disorders, but not in scarlet fever. The course of the disease in the case of the youngest child was not attended by as much urinary irritation as in that of the eldest, but as a set-off she had a fetid discharge from her ear, following the abscess mentioned, lasting all through the period of desquamation.

4. The form of illness which manifested itself in the case of the mother seems to have a significance. It presented as much the character of diphtheria as most cases I have seen, except that it showed no decided throat exudations. This I fancied was partially, if not wholly, due to her freely and frequently using antiseptic gargles. That she contracted the illness from one or other of her daughters, while attending them, appears to me to be beyond a reasonable doubt. But their illness was scarlatinal, and gave rise in their brother to what I may term a benign case of the like nature, while the same source of origin induced in the mother a diphtheritic form. It may be that this was only an instance of reversion, adaptation to its surroundings on the part of the morbid force, the receiving body not being suitable for a scarlatinal manifestation.

Wellington, Somerset.

IODOFORM IN OPERATIVE SURGERY.

By A. F. MCGILL, F.R.C.S.,

Assistant-Surgeon to the Leeds General Infirmary.

THE use of iodoform in operative surgery is comparatively recent, and at present is by no means general, as many surgeons are deterred from using it by the supposed risks of iodoform poisoning. Several deaths have been reported from this cause, and toxic symptoms have been by no means unfrequent, but when we learn that surgeons have been in the habit of packing from eighty to three hundred grammes of iodoform into newly made wounds, this is perhaps not to be wondered at. After six months' experience of its use, I have come to the conclusion that its dangers have been much exaggerated, and that when properly used it is a most valuable agent.

Iodoform may be applied with advantage in four different classes of cases: (1) In old septic wounds, the result of inflammation or of traumatism; (2)

in recent wounds, in the infliction of which it is impossible for the surgeon to adopt full antiseptic precautions; (3) in wounds near any of the natural orifices of the body; and (4) as an external application combined with other antiseptic dressings.

1. It has always been a matter of extreme difficulty to render putrid wounds aseptic: in some cases, as, for example, in large abscess cavities, it is well nigh impossible; when, however, the wound is of comparatively small size, iodoform may be used with great advantage. Owing to its great insolubility, its antiseptic action continues for a long time, and thus is very efficacious in destroying organisms. The following case is so remarkable that it seems worth recording:—

A child, aged five years, was brought to see me at the Leeds Public Dispensary on Dec. 6th last year. The mother stated that the child had been ill for five weeks, that the left leg had been much swollen till a fortnight before, when it burst, and discharged a large quantity of matter. On examination the leg and lower part of the thigh were seen to be much enlarged, and a red blush extended from the foot to above the knee; there was an opening which would admit the finger tip on the outer aspect of the leg at the junction of the middle and lower thirds, which was discharging unhealthy-looking fetid pus. On passing a probe, dead bone was detected. A pair of small sequestrum forceps were passed through the wound, and a sequestrum, which involved the whole shaft of the fibula for about an inch, was removed in fragments. The wound was then filled with iodoform, and dressed with a large pad of salicylic silk. This dressing was not removed for a week. The wound was then almost closed, the redness and cedema had entirely disappeared; the dressing was renewed as before. In another week the wound was perfectly healed, and the child practically well.

2. In private practice, and more especially in country practice, it often happens that it is impossible to adopt antiseptics in their entirety, and the spray is often of necessity omitted. Under these circumstances it is important to use an antiseptic whose action is prolonged for a considerable time. It is in this class of cases that poisoning caused by the absorption of iodoform is most to be feared; the drug must therefore be employed sparingly, and rubbed with the finger over the whole of the raw surface; indeed it is unnecessary to use a large quantity, as a small amount seems to answer every purpose. I have not as yet seen any evil arise from its use when applied in this manner. It might be supposed that healing by the first intention would be prevented, but this is not the case, as I have seen many cases treated in this way heal immediately in whole or in part. The treatment of small abscesses, whether connected with enlarged lymphatic glands or simple in their origin, is much facilitated by an iodoform dressing. The abscess having been opened its cavity is filled with the powder and a salicylic silk dressing applied; this need not be disturbed for a week, when it can be renewed if necessary. The advantages of this method of treatment in out-patient hospital practice are obvious; the results obtained are excellent.

3. Ordinary antiseptic dressings are, as is well known, inapplicable in operations near any of the natural orifices of the body, and also in the operation of colotomy and others of a like nature. In these cases iodoform may be used either in powder or mixed with glycerine in the proportion of one part to eight. In a patient on whom I recently opened the colon in the left lumbar region this use of the drug was found of great service. In another case, after tying a large mass of hemorrhoids, I found that separation was delayed beyond the

usual time; but the putridity which usually occurs under these circumstances was entirely prevented by painting with the mixture of iodoform and glycerine mentioned above.

4. Iodoform may be used as an adjunct to other antiseptic dressings in two ways—either to purify the skin, or to increase the antiseptic power of the dressing employed. The importance of having the skin surgically clean cannot be too strongly insisted upon, the presence of organisms on the skin being one of the most frequent sources of wound infection. This has been particularly insisted on by Dr. Ogston, who has shown that micrococci are found in great numbers in the ducts of the sweat-glands, and that dangerous consequences may supervene owing to micrococcal infection. With the object of reducing this risk to a minimum I have lately used a thin iodoform ointment or pomade, using it as an inunction to all parts in the neighborhood of the wound. By adding tragacanth powder to glycerine, in the proportion of twenty or thirty grains to the ounce, a convenient basis is obtained, to which iodoform can be added in any desired proportion; a drachm to the ounce seems to answer every purpose. With the object of increasing the power of the dressing employed, iodoform may be used freely external to the wound. The dressing is applied in the following manner:—The operation having been completed with the usual antiseptic precautions, a strip of gauze is dipped in carbolized water and sprinkled thickly with iodoform; this is applied to the edge of the wound over the sutures. A handful of salicylic silk is then taken, and about a teaspoonful of iodoform is poured upon it; this is placed over the end of the drainage-tube. If it is probable that the discharge will be large in amount, the skin is powdered with iodoform. A pepper-box may be conveniently used for this purpose, and silk freely used wherever it is expected that discharge will collect. A pad made of silk placed between gauze, and large enough to overlap the wound for eighteen inches in every direction, is then fixed to the part with gauze bandages; the edges are secured with elastic webbing or with strapping. A first dressing applied in this manner need not usually be disturbed for from five to eight days, and subsequent dressings may be left even longer. This mode of treating wounds is in practice found to answer admirably, and this is what we would expect on theoretic grounds, for it fulfils two conditions of primary importance: it keeps the wound and its discharges aseptic and enables it to be kept at rest. An enlarged experience may possibly make me change my opinion as to the value of iodoform; at present I consider it a perfectly safe and reliable antiseptic.

Leeds.

ON A CASE OF HÆMORRHAGE FROM THE MOUTH, NOSE, AND LUNGS.

By WM. O'NEILL, M.D., M.C., M.R.C.P. Lond.,

Physician to the Lincoln Lunatic Hospital, etc.

I THINK the following case of hæmorrhage, from its rarity as well as from the several interesting features which it possesses, is worth recording. I therefore venture to narrate it in as brief terms as the case will admit.

On February 2d, 1881, I was asked to see a man whom I had previously attended, and who had for some months indulged rather freely in tippling. On this occasion he was suffering from nervous symptoms as well as from a cough, the result he said of a cold caught some days before. He came of a healthy stock; all his brothers and sisters as

well as his father and mother were living; the father has, however, of late years suffered from chronic rheumatism and from occasional attacks of bronchitis. The patient, who was married, was thirty-six years of age, and in comfortable circumstances. He looked ill, had lost flesh and strength, and was much depressed in spirits. His cough was troublesome, and his expectoration was frothy and slightly tinged with blood. A physical examination of the chest disclosed some râles at the apices of both lungs, especially at the apex of the left lung, over which there was a little dulness on percussion. The sounds of the heart were normal; the pulse was 80 in the minute, and weak; the temperature of the body was a little under 100°. The temperature and the pulse did not vary much for the first few weeks; but when the prostration was great the pulse increased in frequency, especially on exertion or on emotion. The urine was healthy, but the whole digestive system was much deranged. The patient's food consisted for the most part of beef, mutton, bacon, bread, tea, and coffee. Sometimes he ate a little vegetables on Sundays, but he told me that he was "no vegetable man." On the 6th my attention was drawn to the patient's mouth in consequence of his complaining of pain and tenderness in it. On examination I found the mucous membrane of the gums and mouth, extending to the pharynx, red and swollen. Spots could be seen on the gums and on several parts of the mouth darker and more congested than the surrounding parts, from which a little blood was escaping. The bleeding slowly but persistently increased, and, to make matters worse, the mucous membrane of the nostrils about the 12th of the month assumed the same kind of hæmorrhagic action. From this time the hæmorrhage from the mouth, nose, and lungs continued almost uninterruptedly, without increasing or diminishing to any great extent, until the 28th, when it received a check, but the hæmorrhage in its gradual decline lasted ten or twelve days longer. The blood which escaped from the patient's mouth was diluted with a watery fluid, as if ptyalism was taking place at the same time. The blood from the nose, although watery, was richer in red particles than that coming from the mouth; nevertheless, it rarely formed clots, even when the nostrils were plugged. It was difficult to ascertain with exactness the amount of blood which came from the lungs, but it was not great. The greater quantity flowed from the mouth, and the loss of blood from it was chiefly instrumental in producing anæmia, which from day to day became more pronounced. This was not a case of hæmophilia, as neither the patient nor any of his immediate relations has at any time been subject to recurrent hæmorrhage. From the dislike the patient had for vegetable food it might naturally be supposed that he was suffering from scurvy, and to a certain extent this probably was the fact. Still the affection differed from well-marked scurvy in the absence of bleeding from the stomach, bowels, bladder, and kidneys, and also in the absence of ecchymosis and petechiæ on the skin. The disease differed also in some respects from scurvy in the length of time the bleeding continued; for if the affection had been scurvy pure and simple, the hæmorrhage would hardly have been so rebellious to treatment. The bleeding was the outcome I believe of three causes, which had been operating on the patient at the same time—namely, a consumptive cachexia, an alcoholic cachexia, and a scorbutic cachexia, all these states of the system combining to produce a morbid condition of the blood conducing to hæmorrhage. Cases resembling this, doubtless, were frequent enough when hard drinking of un-

diluted stimulants was more the fashion than it is at the present time, and when scurvy was prevalent in the land; but since scurvy, like ague, has almost disappeared from the country the examples of hæmorrhage of this kind which present themselves are few and far between.

In a case similar to the one under consideration, in which a suspicion exists of a scorbutic taint, great attention should be paid to the proper selection of kitchen physic. This patient was ordered to take in the way of food broths, beef-tea, bread-and-milk, mashed potatoes with butter, green vegetables, and milk or lemonade for drink. I consider there are no better antiscorbutics than good potatoes and milk. I have observed that those who live for the most part on potatoes, milk, butter, and eggs, and who partake of flesh meat perhaps once a week, are healthy and robust, and singularly free from skin disease. I think a dietary of this kind preferable as a giver of health and strength to one composed of bread, tea, coffee, and fat bacon. People who live much on tea and coffee would do well to eat frequently with these beverages potato-cake, a most delicious tea-cake when properly made and cooked; a palatable cake suitable for diabetic patients can also be made by treating grated raw potatoes in a way that removes the starch from the gluten. In some skin diseases potato-juice diluted and flavored is of considerable value as a therapeutic agent.

In the way of treatment by drugs, the patient took at the outset gallic acid and fluid extract of ergot in a mixture. This failing to stop the bleeding, he next took the liquid extract of vinca major and tincture of larch. Anæmia coming on, he was ordered in succession iron, alum, solution of the pernitrate of iron, and a mixture composed of tincture of muriate of iron, chlorate of potash, and quina. This combination answered well, and was taken for several weeks. Lastly, he took for a month or two chloride of calcium in a mixture. He used several astringent gargles; but the gargle that answered best was a solution of perchloride of iron, glycerine, and water. This solution was also used for plugging the nostrils.

In conclusion, I may add that the patient was under treatment for about three months, and at the end of that time he seemed to be in fairly good health; and in this state he continued till he had occasion to leave home a short time ago, when, one morning, in the town to which he had gone, he was found dead in bed. A post-mortem having been made, the lungs presented a most engorged appearance; the heart was enlarged and very flaccid, being quite empty of blood; the left lung was thoroughly adherent to the walls of the chest, the right lung partly so; and the bowels much inflamed.

Lincoln.

BOOKS FOR PATIENTS IN HOSPITALS.—An appeal for books, magazines, and other light literature for the use of adult patients in our metropolitan hospitals, and for toys, children's books, etc., for the use of occupants of the children's wards in the same institutions, has been issued. The request is worthy of attention, but the statement that many of the books are given away by the patients to their friends on visiting days is surely an error. The books are given to the hospital, not to the patients, and are, or ought to be, the property of the institution and not of an individual. In some cases, too, there may be risk of infection being carried in this manner from wards to the outer world.

A Mirror OF HOSPITAL PRACTICE BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendia, nisi quamplurimas
et morborum et dissectionum historias, tum aliorum tum proprias
collectas habere, et inter se comparare.—MORGAGNI *De Sed. et

ST. THOMAS'S HOSPITAL.

INTESTINAL OBSTRUCTION COMING ON FOUR YEARS
AFTER THE OPERATION OF OVIARTOMY; ABDOMINAL
SECTION AND FORMATION OF ARTIFICIAL ANUS BY
ATTACHMENT OF LOWER END OF ILEUM TO WOUND;
RELIEF; DEATH FROM EXHAUSTION TWENTY-TWO DAYS
AFTERWARDS.

(Under the care of Mr. SYDNEY JONES.)

For the report of the following notes we are indebted to Mr. W. H. Battle, surgical registrar.

E. J.—, aged forty-three, married, was admitted on June 21st, 1882. In 1878 Mr. Knowsley Thornton removed tumours of both ovaries of papillomatous character, and also a small solid growth from the broad ligament; a similar one was left behind in Douglas's pouch. The woman made a good recovery, but she continued to have trouble with the bowels. For the first two years the constipation was almost constant, amounting once or twice almost to actual obstruction, relieved by the administration of atropine and morphia; but for seven months before admission there had been almost incessant diarrhoea, and the woman had not passed a single formed motion during that time. She had lost flesh considerably. For the last five weeks she had been troubled with frequent attacks of severe cramping pain in the abdomen, attended with marked movements of the intestines. During this time she was able to take very little food at all. About three weeks before admission she had for two days a violent attack of retching and vomiting, and at that time passed a great deal of blood-stained mucus from the bowel. On June 19th she had a more severe attack of pain than usual, and from that evening at six o'clock until admission there had been no action of the bowels, and the pain had increased. At twelve o'clock on the 21st she had a very violent attack of pain attended with vomiting, the ejected matter being brown and very offensive.

When admitted the patient was emaciated and pale, with an anxious look, and complained of the pain in her abdomen and of sickness. The abdomen was much distended, and the outline of some intestinal coils was clearly marked and large. There was the line of cicatrix remaining from the previous operation, but it was quite healthy. On examination per rectum a tumour could be felt behind the uterus, filling up Douglas's pouch. The vomiting had temporarily ceased; the tongue was moist, and her temperature was 98° 6". She was accordingly ordered a pill containing half a grain of powdered opium and one-third of a grain of the extract of belladonna to be taken every three hours, milk in small quantities and ice only being allowed, and an application of belladonna and glycerine placed over the abdomen. She was twice sick during the night; the vomit was not offensive, though brown. The patient did not sleep, but was fairly free from pain, though at intervals she had sharp bearing down pains. Next morning (June

22nd) the tongue was rather furred, but moist. She was given a pill containing one-fourth of the extract of belladonna every three hours.

June 23rd: The abdomen was less tense. She had had no sickness since the 21st. Had passed much flatus by the bowel, but no solid feces. She had no pain. On the 27th the patient was much better; had lost the anxious look, and was in good spirits; bowels acting pretty freely. At her own request she was allowed chicken, which she ate next day (28th) at dinner time. In the evening she was seized with severe pain in the abdomen, which she referred to the region of the umbilicus. The abdomen was distended and tympanitic, and she became considerably collapsed, frequently vomiting offensive fluid, though the odor was not fecal. The face looked pinched and livid, whilst her pulse became rapid and weak; and it was evident that operation was advisable now if anything was to be attempted. Accordingly, at 10.30 p.m., with antiseptic precautions, Mr. Sydney Jones made an incision in the median line, about four inches in length, between the umbilicus and pubes. The peritoneum having been divided on a director, the finger was introduced, and a considerable quantity of sero-sanguineous fluid escaped. A largely distended coil of intestine appeared. No band was discovered, though there was much scattered deposit over the peritoneum. The incision was enlarged upwards, and a band was found passing from near the umbilicus towards the left iliac fossa. This, however, did not appear to constrict any definite portion. By this time a large amount of intestine was exposed, a good deal being out of the wound, and greatly hampering further search from its distended condition. It was, therefore, tapped, and a large amount of pale-colored thin fluid drawn off. The intestine having collapsed to some extent permitted a further search to be made, and it was found that there was great matting of the ileum in the neighborhood of the cæcum, binding it down, and, doubtless, causing the obstruction; it was quite impossible to free this. It was also found that the band before mentioned compressed the ileum above sufficiently to prevent feces passing through. This was therefore divided between a double ligature; it was very thick, but was quite imperforate. The intestine had been tapped a short distance above the obstruction. The part which had been tapped was retained outside, the opening enlarged and stitched to the abdominal wall so as to form an artificial anus in the median line. The carbolic spray was used throughout, but the usual full dressing was not employed; the wound was dressed with lint soaked in carbolic oil, and a pad of salicylic wool placed over the opening. The patient suffered much from shock. A brandy enema and a subcutaneous injection of ammonia were given towards the end of the time.—29th: After the operation patient was sick four times between 1 a.m. and 5 a.m.; but she rallied rapidly and took nourishment in the form of Brand's essence and brandy-and-soda in small quantities all through the night. She had six minims of morphia subcutaneously, but had very little pain at all. At 5 a.m. her temperature was 99°2'. At this time the fecal matter came away from the artificial anus for the first time. At 4 p.m. she was quite comfortable, taking her nourishment well. Fæcal matter was coming away freely. Temperature 99°8'; pulse 95; tongue fairly moist. Eight ounces of urine drawn off at 10 a.m. She perspired a great deal, and was somewhat drowsy, but much relieved. The temperature rose to 100°8' during the night, and the patient was restless and in much pain; but she slept at intervals, though never for long. On the following morning she was evidently weaker. Pulse feeble

and respiration shallow and with some difficulty. Tongue red, dry, and sore; bowels were much relaxed in the night; perspiring freely. She became quiet and composed after the administration of five minims of morphia subcutaneously. Nutrient enemata were commenced and continued every four hours. They were composed of three ounces of beef-tea, the yolk of an egg, half a drachm of brandy, ten grains of pepsin, and three grains of pancreatin.

On July 1st the patient passed a comfortable night after injection of morphia; was stronger and breathing was easier. Complained chiefly of soreness of her tongue; ordered borax and honey. On the 2nd, as the nutrient enemata were returned, they were discontinued. Tongue clean, of raw ham appearance and fissured; soreness relieved by application. Free from pain, only complained of occasional faintness. No distension of the abdomen, though a good deal of tenderness. The wound looked well, and there was free discharge from the opening. Urine drawn off by catheter since the operation. Pulse 120, of fair strength. Is taking champagne, brandy, and beef-jelly. In the evening she became worse and frequently vomited, and only slept about an hour during the night; she was ordered half a grain of opium pill three times a day.—On the following morning a mixture containing carbonate of bismuth and dilute hydrocyanic acid was given three times a day; and as everything given by the mouth was rejected, the nutrient enemata were again tried, but were only retained about an hour and a half. There was less fecal discharge from the artificial anus, and the patient was decidedly weaker, and the temperature subnormal, 97°6'. There was no sickness after 10 p.m. Only a little iced brandy-and-water allowed by the mouth, and the enemata were continued. Temperature 99°2'. On the 6th she had a slight return of the sickness, and was allowed nothing more by the mouth; had slept fairly after injections of morphia. Temperature 97°4'; was without pain. Wound redressed; stitches removed; union not good; parts supported by strapping. On the 10th the tongue was still furred and rather glazed; she had vomited again; there was a free discharge from the artificial anus, and the patient appeared fairly well. Temperature 98°8'; pulse 120, stronger. Enemata every three hours; these were retained fairly. On the 14th, though she had slept fairly well, she was weaker and unable to retain the nutrient enemata. A little claret by the mouth was tried, but it caused vomiting. Small quantities of fecal matter passed from the wound. Pulse 120, weaker. Temperature 99°2'.—15th: Pulse 120; temperature 98°. Tongue dry and rather glazed. No vomiting. Slept in snatches, and her mind was not so clear as usual.—17th: Much weaker. Pulse 108, feeble. No pain. Nutrient enemata not retained longer than an hour. Temperature 96°2'.

On the 18th she had slept well, and was somewhat better, though the pulse was 120, and still feeble; had retained one enema, but only takes a little brandy and soda-water by the mouth. Temperature 96°4' to 98°.—19th: During the day there was increasing weakness, the evening temperature rose to 102°4', and she died soon after midnight. Before the operation the temperature varied from 97°4' to 99°2'. The evening temperature after operation was 98°6'. Next day it reached 100°8'; but did not again exceed 99°6' until the evening of the 19th, when, as before mentioned, it was 102°4'. The morning temperature was usually subnormal, and on one occasion was only 96°.

A post-mortem examination was made a few hours after death. There were a few adhesions at the apex of the right lung; thoracic organs other-

wise healthy; the kidneys and spleen normal; the liver small, friable, and adherent to the under surface of the diaphragm; gall-bladder much distended. The coils of intestine were slightly glued together; there was recent peritonitis. The artificial anus had been established in the small intestine twenty-nine inches from the ileo-cæcal valve; the gut above was quite patent and filled with bilious fluid fæces as far as the orifice made. The lower part of the ileum and the cæcum were matted together by glandular and inflammatory infiltration. The rectum was compressed and adherent to the posterior wall of the uterus and upper part of the vagina. On separating them a small abscess cavity containing about four ounces of pus was found. In Douglas's pouch were three or four papillary growths about the size of filberts. They were hard, nodular, and seemed to spring from the region of the left ovary and broad ligament. The position of the left ovary was occupied by a firm mass of fibrous cicatricial tissue from which grew one of the papillary growths.

SHEFFIELD PUBLIC HOSPITAL AND DISPENSARY.

NOTES ON A CASE OF IMPACTION OF A FOREIGN BODY IN THE AIR-PASSAGES; TRACHEOTOMY; RECOVERY.

(Under the care of Dr. KEELING.)

For the following notes we are indebted to Mr. G. F. Gubbin, house-surgeon.

W. P—, a boy, aged three years and a half, was brought to the hospital on Dec. 11th, 1882, by his mother, who said that whilst at school another boy had attempted to make her son swallow a bead.

On admission there was considerable dyspnoea, with cough and hoarseness, but a little while afterwards a marked remission of the symptoms occurred. Dr. Keeling performed laryngo-tracheotomy, but was unable to discover any obstructing body in the larynx; the lips of the wound in the trachea were separated, and the child was sent to bed. Examination of the chest made it quite evident that there was an obstruction to the entrance of air into the left lung. On Dec. 14th (the third day after the accident) a violent attack of coughing came on, accompanied by much dyspnoea, and it was supposed that the foreign body had become dislodged; consequently a pair of dressing forceps were introduced into the wound in the trachea in order to still further dilate it, and directly afterwards an expiratory effort expelled the foreign body through the wound. Slight inflammation at the root of the left lung followed, but this soon disappeared. The wound in the trachea healed readily, and the patient was discharged from the hospital on Jan. 1st, 1883. The foreign body proved to be a pear-shaped glass pendant, with a loop of brass wire attached to it, weighing fourteen grains; it was considered to be a portion of an earring.

GUY'S HOSPITAL.

THREE CASES OF COMPLICATED FRACTURE.

(Under the care of Mr. BRYANT.)

CASE 1. *Fracture of Tibia and Fibula; Division of Tendo Achillis to correct Displacement; Recovery with good Limb.* (Reported by Mr. Paliologus.)—Walter W—, aged twenty-five, was admitted on May 19th, 1881, into Accident ward. The patient, a plate-layer, was employed at his work relaying a sleeper, when a passing engine caught the end of the sleeper, drove it against his leg, and knocked him over.

On admission, there was a simple fracture of the tibia and fibula of the left leg about the middle of the lower third. The fracture was oblique in direction from above backwards and downwards. The leg was put up in a back and two side splints, and an ice-bag applied.

May 22nd: Lower fragment projecting forwards. Splints reapplied.—27th: Fragments still in bad position. Under chloroform, the tendo Achillis was divided and the bones brought into a better position, but the lower fragment still projected upwards and inwards. Wound sealed with tincture of benzoin.

June 8th: Fragments in good position. A pad of cotton-wool has been placed on the outer side of the upper fragment and inner side of the lower.

July 6th: Fragments in very good position, so that the line of fracture cannot be made out.—9th: Splints removed. A slight wound due to the pressure of the splints was found on the back of the calf, and the whole leg was a good deal swollen.—18th: Bavarian splint put on. Very good position.

CASE 2. *Fracture of Lower End of Humerus; Occlusion of Brachial Artery; Relieved.* (Reported by Mr. Winter.)—Jas. H—, aged fourteen, was admitted into Accident ward on July 13th, 1881. The boy was playing in a field with some other boys when he fell on his hand, the arm being outstretched. The fall caused him a good deal of pain, and soon afterwards he noticed a swelling and that his arm was becoming red. It was comparatively free from pain when at rest, but caused acute pain when moved.

On admission the elbow was very swollen and inflamed. There was no pulsation of the radial artery and the hand was cold. The arm was placed in a flexed position and kept so by sand-bags and an ice-bag was applied.

July 14th: A faint pulsation can be felt in the radial artery.—15th: The olecranon process can be felt to be displaced backwards. There is a good deal of swelling round the joint, and the skin is bluish over the injured part. The pulsation in the radial is still faint, but more distinct than yesterday. No pulsation can be felt in the swelling at the elbow.—18th: Swelling subsiding, some oedema of wrist.—19th: The internal condyle is quite distinct, and can be moved by grasping it.—22nd: No pulse to be felt in radial artery.—24th: The arm was flexed to a little more than a right angle and an internal angular splint applied.—26th: Discharged.

CASE 3. *Compound Subastragloid Dislocation inwards of Foot; Fracture of head of Astragalus; Removal of Head of Bone and Reduction; Recovery, with some Movement of Limb.* (Reported by Mr. Winter.) Michael C—, aged thirty-seven, a laborer, was admitted into Accident ward on Aug. 11th, 1881. The patient fell some ten or twelve feet upon his feet.

On admission there was considerable laceration on the outer side of the left ankle, through which the head of the astragalus projected, the whole of the foot beneath the bone having been displaced inwards. It was at first thought by some that the case was one of dislocation of the astragalus. The patient was taken immediately to the theatre, when the head of the astragalus was found to be crushed at one point, and reduction was impossible. Part of the head of the astragalus was therefore sawn off, and reduction effected. There was very little hemorrhage. The wound on the outer side of the ankle was about three or four inches long, with clean cut edges. These edges were brought together with two or three silver sutures. The joint was well washed out with

iodine lotion. A drainage-tube was put in and the foot was put upon a posterior splint. The wound was dressed with terebene and oil.

Aug. 14th: Parts round the wound are red, glazed, and cedematous.—17th: Had a slight attack of delirium tremens last night.—18th: Red blush around the wound diminished.—22nd: Redness decreased. The discharge is somewhat serous in character; there is no burrowing.—23rd: Redness disappearing; discharge healthy.—31st: There was some redness and tension above the external malleolus, as if there were some inflammation extending up the sheaths of the peronii muscles. An incision was made about half an inch above the external malleolus to relieve tension.

Sept. 7th: Wounds granulating; rather more discharge of pus.—20th: Wound enlarged to give vent to pus.

Oct. 5th: There is cedema extending to the upper half of the leg, and considerable swelling about the ankle-joint. The wound does not discharge, and has a healthy appearance.

Nov. 1st: Drainage-tube discarded.—2nd: There is great swelling of the ankle on inner side; the incision is healed, but in front and behind there is a rounded, soft, elastic swelling, like that seen in pulpy disease. A drainage-tube is inserted above the malleolus, and here there is some redness of the skin, and cedema extending half way up the leg.—9th: Much less swelling of the leg.—15th: Wounds are now quite healed up.—25th: A constant current was ordered on Oct. 15th to be applied to the left arm, as the patient had some wasting of the muscles due to some old injury. Under this treatment the muscles have increased in size, and the patient has more use of the limb.

Dec. 9th: A Bavarian splint was applied.—17th: Discharged.

QUEEN'S HOSPITAL, BIRMINGHAM.

NEPHROTOMY FOR RENAL CALCULUS; NO STONE FOUND;
RECOVERY; REMARKS.

(Under the care of Mr. JORDAN LLOYD.)

CATHERINE S—, aged twenty-nine years, married, was admitted on Dec. 19th, 1882. She dated her illness from an attack, ten years ago, characterized by the sudden onset of pain in the right loin of excruciating severity and attended with vomiting; this lasted for about a fortnight. Shortly after this she noticed that her urine smelt badly and contained a yellow deposit. This persisted at the time of admission. She came first under Mr. Lloyd's care in February, 1881, her chief symptoms being lumbar pain, increased by exertion, fetid urine, and frequent micturition. Under ether her bladder, uterus, and rectum were examined, but nothing wrong was found. She had no lumbar swelling. Her urine was acid and contained pus. The bladder was washed out with an injection of dilute nitric acid.

In January, 1882, she had an attack of pain of neuralgic character in the neighborhood of the right tuber ischii which lasted three months. On Dec. 10th Mr. Lloyd was asked to see her in consultation with Mr. Hugh Thomas, who was then her attendant. She complained of supra-pelvic pain and tenderness; frequent micturition, and the same lumbar pain as before. On examining the right loin something was felt to slip from under the fingers, she at the same time complaining of a sharp stabbing pain. The urine was fetid with a deposit of pus and ropy mucus.

On admission it was recorded that she was a healthy looking woman, and with the exception of her present illness had always been well. She complained of severe pains in the right loin, which

extended from the groin into the labium, and also down the back of the thigh; they were increased by exertion and prevented her walking any considerable distance. Her urine was faintly alkaline, sp. gr. 1014; it contained a small quantity of albumen and gave a reaction to the guaiacum blood test. There was a deposit of pinkish ropy mucus and pus. Microscopically triple phosphates, mucus, pus, and shrivelled blood-corpuscles were seen. She got thinner and all her symptoms slowly became worse.

Dec. 26th, 1882: Under ether Mr. Lloyd exposed the kidney through an oblique four-inch incision about three-quarters of an inch below the last rib. The centre of this incision lay a little behind Allingham's line for the colon, and was directly over the kidney. The gland was not fixed, but moved very freely up and down with respiration. It looked quite healthy at its lower half, which presented in the wound. No resistance could be felt in it. It was punctured in three places with an acupuncture needle, a gritty sensation attending the last insertion. The presence of a stone being doubtful, an excision was made through the kidney substance and the whole pelvis explored with the finger, but nothing was found. The hæmorrhage was small in amount and ceased spontaneously almost directly. A drainage-tube was inserted to the bottom of the wound and its lips brought together with silver sutures. There was not more than two ounces of blood lost throughout the operation, which was conducted on Listerian principles except that the lotions were more freely diluted.—27th: Passed a fair night, free from pain; was sick for several hours after the anæsthetic; has passed water containing hardly a trace of blood; wound dressed, the dressings being soaked with thick red fluid; no urea could be detected in the discharges. Evening temperature 103°; pulse 120; respiration 30.—28th: Dressed; she feels comfortable; menstrual flow came on to-day. Temperature at night 104°.—30th: Sutures removed, the wound being healed except at drain. There was a free watery discharge at first. Antiseptics were discontinued until Jan. 22nd, 1883, and two days later she left the hospital, having experienced none of her old pains since the operation. Urine: reaction neutral; sp. gr. 1010; trace of albumen; a few pus and mucous corpuscles and crystals of triple phosphates; there was a slightly fetid odor.

On March 8th, 1883, Mr. Hugh Thomas wrote that his patient was going about her work as usual and has had no return of the painful symptoms, but that her urine continues rather unpleasant.

Remarks by Mr. JORDAN LLOYD.—Since no stone was found in this case I am at a loss to account for the patient's symptoms. That she has a lesion attended by the discharge of pus into her urinary tract there can be no doubt. The chronicity of the pyuria, with the character of the pain, shooting from the loin into the labium and down the thigh, the exaggeration after exertion, the pain on pressure over the right kidney, and the trace of blood in the urine, together led me, so it has turned out, into a wrong diagnosis. I digitally examined the whole surface of the bladder for ulcer, stone and fistulous opening, on two different occasions and found nothing. The rectum and uterus gave negative results to the most elaborate and careful investigation. The at times intensely fetid urine suggested a possible communication between the intestinal and urinary tracts at some part of their course. There has not been the slightest traces of fæces or gas, however, in the urine. Whatever her disease is, I feel sure it is situated somewhere between the bladder and the kidney substance, and is out of the reach of surgical investigation. It is curious that the operation appears, up to the

present, to have relieved her painful symptoms. Similar effects have been previously reported. I have within the last three months assisted at three other kidney operations—a nephrotomy, a nephrolithotomy, and a nephrectomy, and have been struck by certain facts common to all of them. First, the reliability of Allingham's line as a guide to the gland. Secondly, the distinctness of a layer of fascia which is found really in the kidney fat, lying deeper than the well-known layer which passes in front of the quadratus lumborum muscle. It may easily be mistaken for peritoneum. Thirdly, the mobility of the gland during respiration. Fourthly, the rapid cessation of hæmorrhage from the wounded viscus. In my own case also I was struck by the distinctness with which I could recognize the entrance of the needle into the cavity of the pelvis of the kidney, and in both nephrectomies I was surprised by the almost entire absence of blood from the urine passed after the operation. The conclusions I have arrived at with this personal experience, which is strengthened by the published cases of others, is that these operations are not only justifiable, but are fairly simple and tolerably safe, and that kidney surgery is for the future an established fact.

CLAYTON HOSPITAL, WAKEFIELD.

CASE OF OCCLUSION OF THE VAGINA FOLLOWING PARTURITION, CAUSING RETENTION OF MENSES; EVACUATION; CURE.

(Under the care of Dr. HOLDSWORTH.)

FOR the notes of the following case we are indebted to Mr. D'Arcy B. Carter, resident surgeon.

Alice H—, married, aged twenty-five, presented herself for examination in the out-patients' room on April 5th, 1881, with the following history:—Nine months ago she was confined of her first child; the labour lasted thirty-six hours, and was a very tedious one, forceps not being used; the child was full term and still-born. Catamenia quite regular up to the commencement of pregnancy, but have never reappeared. There was no dyspareunia before pregnancy, but since her confinement she has been unable to live with her husband. A month after her confinement, at the time corresponding with her menstrual period, she felt very sick and had pains in her back and down her legs, which lasted five or six days, but she did not see any menstrual fluid. These symptoms have reappeared every month at the time corresponding with her former menstrual period, but have gradually got more severe each time.

She was admitted on April 14th, 1881, about the time corresponding with her menstrual period. It was noted:—She is a well-developed but anæmic-looking woman. The breasts are well formed, and there is abundance of hair both in the axillæ and on the vulva. On examination per vaginam an obstruction can be felt at about the lower third of the vaginal canal, completely obliterating the external orifice; the obstruction is tense and elastic, and is continuous with the walls of the vagina. On examination per rectum an elastic swelling can be felt anteriorly, partially blocking up the canal. She has had no difficulty with her water, but has had difficulty in keeping her bowels regularly open. The catheter was passed, and about two ounces of normal urine drawn off. On the evening of admission the swelling was punctured with a No. 2 trocar and cannula, which immediately allowed to escape a dark treacley, grumous-looking fluid; a vessel was placed under the cannula, and the fluid allowed to escape gradually.—15th, 9 A.M.: About fourteen ounces of fluid have

escaped during the night, and she feels more comfortable; temperature 98.4° F. 4 P.M.: About three ounces more of the fluid have escaped during the day. It was now decided to enlarge the opening a little. A probe having been passed through the cannula, which was then withdrawn, a hollow sea-tangle tent was then passed over the probe as it was drawn out. The tent was then secured outside the vagina to prevent its passing through into the vagina on the inner side of the obstruction.—16th, 9 A.M.: The tent removed, and a larger sized one replaced. There has been a little discharge through and by the side of the tent during the night; temperature normal. 7 P.M.: There is still a small quantity of fluid escaping. The tent was removed and replaced by one a size larger. She has no feeling of sickness or headache; temperature 101° F. The discharge not offensive.—17th, 9 A.M.: The tent removed. There is now an opening large enough to admit the finger. The obstruction seems to occupy the whole of the middle third of the vagina, and is firmer at the external orifice, having an inclination to readily break down internal orifice. Temperature 100°; no nausea or headache. To be syringed out every four hours with Condy's fluid and warm water by means of a Higginson's enema syringe and a long tube passed through the obstruction.—18th: There is very little discharge; injections to be continued; temperature 98.4°.—19th: The obstruction was notched on both sides with a curved probe-pointed bistoury, and an ordinary-sized rectal bougie passed, which was to be passed daily. Temperature normal.—24th: The bougie does not cause much pain, so ordered to be increased in size. On digital examination, the os uteri feels soft and open.—30th: Two fingers can now be readily passed through the obstruction.

May 7th: Discharged with instructions to take precautions that the obstruction is not allowed to grow up again.

September 7th: She presented herself at the out-patients' department, and says she feels a new woman altogether. Has menstruated three times since she left the hospital; has no dyspareunia.

November 21st, 1882: She again appeared in the out-patient room carrying a child of which she had been delivered two months previously.

ST. BARTHOLOMEW'S HOSPITAL.

A CASE OF CYSTICERCUS IN THE EYE.

(Under the care of Mr. BOWATER VERNON.)

FOR the following notes we are indebted to Dr. W. J. Collins, ophthalmic house-surgeon.

A. F. R—, aged six, a fair-haired, blue-eyed child, the daughter of a laborer living at Holloway, was recently seen at the hospital. The following notes were taken:—She has been suffering, according to the mother's account, from severe headache and night screaming for the last six months, and it has been noticed that the child squinted with the right eye, and has been in the habit of rubbing or covering that eye with her hand. Has not had any fits. The external appearance of the eyes is normal, with the exception of slight external strabismus of the right eye, but she can fix an object with either eye. The media are clear, the tension normal; the vision of the left eye = 5-5, of the right 5-50. On examination with the ophthalmoscope a brilliant white reflex from the posterior pole of the right eye is at once discerned, and on closer examination a sharply defined subglobular mass, about six or seven times the size of the optic disc, is made out, set in the fundus to the outer side of the disc, but projecting into the vitreous and overlapping and obscuring the inner third of

the area of the optic papilla. The outline of the mass is more or less circular everywhere, except at the upper and outer part, where it is rectangular. Along the outer and lower border is seen a crescentic area of a greenish-grey color, but shading off into healthy fundus, and over which small vessels run, and then dip down to pass beneath the white mass, under and through which a very tortuous artery can be seen. Again, at the lower and inner part the retina is raised and detached over a small area of hemispherical shape, as if stretched over some subjacent mass. The optic disc is in a state of intense hyperæmia with effusion, and exhibits a striated woolly appearance; while its vessels are large and tortuous, and in parts buried by the effusion and proliferated fibres through which they run. The diameter of the cystic mass is estimated at nine or ten millimetres, and it is in a plane anterior to the retinal vessels. Nothing, certainly, resembling a head, hooklets, or suckers can be made out, and no spontaneous movements have been observed during any of the many examinations which have been made of it. The remainder of the fundus is healthy, with the exception of two or three hyaline, streaky, and slightly pigmented patches in the choroid. The fundus of the left eye is natural. The child has suffered from threadworms, but there is no history of tapeworm, and a dose of male fern failed to bring any away. The girl has no special predilection for pork, but has partaken of it at various times.

Remarks by Mr. VERNON.—There is not much room for doubt as to the diagnosis, although the movements of the cyst, or the display of the creature's head, which have been relied upon in the previously recorded cases were wanting to make it perfectly clear. No movements were noticed, although the child has been for some weeks under close observation, and the only indication of a head was afforded by a portion of the cyst being more opaque than the rest. Neither could the exact relation of the cyst with the retina be determined; no vessels could be traced upon its surface, although one retinal vessel could be seen through the transparent portion of the projecting vesicles. The general aspect, however, gives one the impression of extensive adhesion to the coats of the fundus. The history of nearly all the cases on record warrants the conclusion that sooner or later this child will lose her eye. The parasite as it grows and shifts its position is likely to excite more or less irritation, soon to be followed by choroidal changes and disorganization of the vitreous humor, entailing the loss of the globe. Vision would probably be destroyed at an early stage, and even the safety of the other eye threatened; so that all treatment should be directed to the removal of the cysticercus by an operation. In cases where the animal has been situated in the anterior portion of the eye or was visible within the pupil, so that it could be reached from the front, the method of operating was tolerably clear; but when it is situated in the fundus as well as firmly attached there, the steps of an operation are not so clear or so well laid down. In more than one case on record a cysticercus has been removed through an opening far back in the sclera. Of the remarkable instance published by Liebreich as occurring in his own practice, unfortunately all details are wanting. In von Graefe's cases (and the great oculist's experience appears to be altogether exceptional), the results were such that he laid down rules for guidance in the future, indicating his opinion that the extraction should be attempted through an enlarged pupil subsequently to the removal of the lens. In all the recorded cases where an operation was performed, the diagnosis of the case admitted of no doubt whatever;

the parasite could be seen to project considerably, and to move within the vitreous chamber; and in nearly all of them there was considerable pain and irritation. In the case of this child, not one of the indications for interference is present, and the operation of making an incision of some extent in the sclerotic, followed by the introduction of forceps or hook, even if the cyst were grasped and removed, would in itself be so full of danger to the eyeball that it should not be attempted save in the last extremity. Probably the time will come when such a proceeding would be indicated, but at the present moment it does not appear to me justifiable. At a later stage there may be a more promising prospect for an operation; but if the eye should become painful, and the safety of the other eye be threatened, it is open to question whether the better plan would not be the enucleation of the entire globe.

LEEDS GENERAL INFIRMARY.

CASES OF CHOREA; VIOLENT MOVEMENTS; TREATMENT WITH LARGE DOSES OF SUCCUS CONII.

(Under the care of Drs. CLIFFORD ALLBUTT, EDDISON, and CHURTON.)

FOR the following notes we are indebted to Mr. J. F. W. Silk, house-physician.

CASE 1. (Under the care of Dr. Clifford Allbutt; from the notes of Dr. A. G. Barrs, late house-physician.)—Joseph W., aged sixteen, admitted on Feb. 15th, 1882. Has had acute rheumatism four times, each attack being followed by chorea. The last attack of acute rheumatism was in December, 1881, and the present choreic condition is of three weeks' duration. The patient is a well-grown, well-nourished lad, the subject of movements of a typically choreic character, affecting the limbs and face, and not more marked on one side of the body than the other.—21st: Has been getting rapidly worse; the movements are now most violent; he cannot be kept in bed; the skin over the bony prominences is becoming chafed; there is slight lividity of the lips; much emotional disturbance, and he has to be fed with nutrient suppositories.

March 1st: Since the administration of the conium on the 21st a steady and uninterrupted amelioration of the condition has set in, but the emotional character continued.

April 25th: Discharged, vastly improved in every respect; the movements, except on excitement, only slight, but he is easily excited. The heart sounds throughout have remained clear.

Between February 15th and 20th the solution of arsenic was prescribed, increased up to thirteen minims every four hours, and, in addition, on the 19th, chloral hydrate (fifteen grains) three times during the day. On February 20th, between 9.30 A.M. and 11.45 P.M. four doses of one-third of a grain of morphia were injected hypodermically. He was somewhat quieter after each of these and subsequent injections, but the improvement was only transitory. On February 21st, between 3 A.M. and 9 P.M., two doses of one-third of a grain of morphia and two of half a grain were exhibited. At 11 A.M. he commenced taking half an ounce of the succus conii every three hours. On the 22nd, between 5.30 A.M. and 9 P.M., three injections of half a grain of morphia were given. The hemlock was continued in the same dose, half an ounce, throughout the day, and was discontinued on the morning of February 23rd. From February 28th to April 20th he took the solution of arsenic up to twelve minims three times a day. This lad was readmitted with a return of the chorea on January 15th 1883, but it was of a much milder type and yielded to ten minim doses of solution of arsenic.

CASE 2. (Under the care of Dr. Eddison; from the notes of Mr. J. H. Naylor, medical assistant.)—Sarah G—, aged nineteen, a servant, admitted Feb. 23rd, 1883, had rheumatic fever six years ago, and again two years ago. After the first attack she had severe general chorea, from which she has never since been entirely free, but which has been more marked during the last month, probably on account of exposure and want of food. The patient was an anæmic, ill-nourished girl. Choreic movements very violent, affecting the arms, legs, face, and body universally. Speech blurred and indistinct; peculiar spasmodic guttural sounds, uttered involuntarily every few minutes. Loud blowing systolic bruit heard over apex of heart, and conducted towards the axilla. Other heart-sounds normal. Amenorrhœa for two months.

March 4th: The patient is getting much more violent; clothes cannot be kept on her bed; she is constantly springing up with an expression of abject terror; has hallucinations about her sister; is fed with difficulty; and sleeps only a few minutes at a time. At 5 p.m., 10.30 p.m., and 2 a.m. of the 5th, one-sixth of a grain of morphia was injected hypodermically, but improvement only slight and transitory.—5th: She commenced taking succus conii in doses of one drachm every hour. After the fourth dose, as no improvement was noticed, it was increased to two drachms, and twenty grains of bromide of potassium added, to be taken every two hours. Some slight improvement followed, and she slept for some few hours at a time; but the movements were still very violent.—8th: At 12.30 p.m., half an ounce of succus conii was given by itself; she fell asleep almost immediately, and slept well and quietly until 6.30 p.m., when the dose was repeated, and she fell asleep again until 5.30 a.m. the following morning. No toxic symptoms were observed, and the drug was continued at intervals until 12.30 p.m. on March 10th; a dose being given whenever the movements showed the slightest tendency to become violent. In all she took six doses of half an ounce each between 12.30 p.m. March 7th and 12.30 p.m. March 10th, when solution of arsenic was substituted.—16th: Movements becoming violent again, half ounce doses of conium every four hours.—24th: In the evening very noisy; movements violent; hallucinations. Conium to be given every two instead of every four hours; immediate improvement.

April 10th: Movements hardly perceptible; has been taking conium (half an ounce) three times a day since March 29th, and is going out in the course of a day or two. Is now menstruating.

CASE 3. (Under the care of Dr. Churton; from the notes of Mr. J. H. Naylor, medical assistant.)—Emily W—, aged twenty-two, weaver, admitted March 9th, 1883. No history of acute rheumatism or other severe illness, and there is no discoverable cause for the present condition. Choreic movements commenced in her left hand at the age of eight, and rapidly extended to the whole of her left side. Between the ages of eight and twenty the chorea was confined to the left side, she was never quite free, but the movements increased during the summer and became much less during the winter months. From the age of twenty until the commencement of the present attack a fortnight ago has been quite free from spasmodic twitchings of any kind. Can think of no determining cause for the present attack, but she knows, and has associated with, Case 2. Is a robust and well-nourished girl of powerful but coarse build. Choreic movements, well marked and universal, of about the same intensity as in Case 2. Muscles of speech and deglutition likewise affected; there is also some reddening and slight excoriation of the

skin over the bony prominences. Heart sounds, menstrual, and other functions, normal.

March 13th: Movements more violent. Succus conii, one drachm, every hour for four doses, then increased to two drachms, twenty grains of bromide of potassium added, and given every four hours.—17th: No improvement, if anything worse. Since midday of 15th has been taking two drachms of conium by itself every two hours, fourteen doses in all. At 9.30 a.m. dose increased to half an ounce every four hours, and at 10 p.m. every two hours. After the dose at midnight she slept well, and on the following morning the movements had been greatly reduced. The drug was given every two hours during the day (18th), and by the evening the movements were hardly appreciable. The improvement was most marked.

April 3rd: Took conium every two hours during the daytime until March 25th, when it was taken every four hours; and the 27th reduced to three times a day, and this morning iron and arsenic were substituted. No toxic effects were ever noticed.—10th: Seen as an out-patient, there is hardly a vestige of any choreic movement left.

Remarks.—These are good examples of the class of cases occasionally met with, in which the choreic movements become so violent as to endanger life. Their chief interest, however, centres upon the use of succus conii, these cases seem to show: 1. That the drug, to be of any service, must be given in large doses. 2. That its action must be sustained by frequent repetitions of the dose at short intervals. The uncertainty of the action of given specimens of succus conii necessitates great care in its administration, and militates against its general adoption. But cases in which neither chloral nor morphia have any effect may arise, and in which, as in the above, succus conii may prove efficacious.

ABERDEEN GENERAL DISPENSARY.

EXTERNAL HÆMORRHOIDS IN A NEW-BORN CHILD.

(Under the care of Dr. FRANCIS OGSTON, junior, and Mr. GEORGE VINCENT.)

At the beginning of February a child three days old was taken to the dispensary by its mother, who stated that she had noticed the child cried very much when its bowels were moved, and that it had a red projecting tumour at the anus.

On examination a bright-scarlet tongue-shaped tumour was seen to spring from the point of union of the mucous membrane of the anus with the skin. It was situated at the left side. At the front part of the anal border a second flatter tumour of the size of a split pea was also found. After a few days' treatment with boracic acid ointment the inflammatory redness had in a great measure subsided, and the larger tongue-like tumour had now changed into a club-shaped unmistakable hæmorrhoid with a narrow pedicle; and the second flatter projection had greatly diminished. A day or two afterwards the larger tumour was removed by surrounding the pedicle with a loop of thread.

Note by Dr. OGSTON.—The earliest case of hæmorrhoids which I can find record of occurred in a child of four months of age, but this seems to have been existent at birth or a few hours after it. It is difficult to account for such a phenomenon thus early in life, for the bowels had all along been moved freely and the stools were of normal color and consistence, a fact which was verified by the bowels being moved while I was examining the child. The icterus neonatorum had never been present. The liver seemed on palpation of normal

size; and the umbilicus cicatrized in a healthy manner. Thus none of the usually given predisposing causes of hæmorrhoids—portal congestion, liver disease, and overloading the rectum with hard feces—were present. The labour, the sixth, had been a perfectly normal one, with head presentation.

PETERSFIELD COTTAGE HOSPITAL.

CASE OF POPLITEAL ANEURISM; FAILURE OF COMPRESSION; ESMARCH'S BANDAGE AND GENUFLEXION; LIGATION OF FEMORAL ARTERY; RECOVERY.

(Under the care of Dr. A. W. LEACHMAN.)

G. A.—, aged thirty-eight, a farm laborer, was admitted on June 3rd, 1882, complaining of pain in the left leg and a swelling behind the knee. His family history was good; he had enjoyed excellent health, had never had syphilis, gout or rheumatism, but had drunk beer freely. Nine or ten weeks ago he was helping to lift a cart wheel out of a rut, when he felt a sudden pain in the calf of the left leg. This passed off in a few days, but two or three weeks afterwards he noticed a swelling behind the left knee which gradually increased in size, and ten days before his admission he was obliged to give up work on account of the pain and swelling of the limb.

On admission a tumour, about the size of a hen's egg, was felt in the left popliteal space with very visible pulsation, and communicating to the hand a rasping thrill. With the stethoscope a rough systolic bruit was heard. The veins over the tumour were swollen, and the leg and foot œdematous. The leg could not be completely flexed or extended. The posterior tibial artery could not be felt at the ankle. Compression of the femoral artery at Poupart's ligament stopped the pulsation in the tumour. The circumference of the sound limb at the knee was 13½ inches, of the affected leg 15 inches. The patient had great pain in the knee, had little appetite, and slept badly. The urine was free from albumen. Perfect rest in bed was enjoined, and iodide of potassium in tengerain doses three times a day, and a diet limited to twelve ounces of solid and half a pint of liquid daily were ordered.

June 18th.—An attempt at genuflexion causing such tension in the aneurism as to threaten rupture, compression of the femoral artery in Scarpa's triangle was kept up by Signoroni's tourniquet and by the fingers alternately for ten hours. The pain caused by this treatment was so severe that chloroform was administered during the last two hours and a half. On discontinuing pressure pulsation returned in the aneurism but in a less degree. Next day Esmarch's bandage was applied tightly from the toes to the lower border of the aneurism, then across the patella to its upper border, whence it was carried for a distance of two-thirds of the length of the thigh, the elastic ligature was then tightly fixed round the thigh, and the bandage removed, the limb being enveloped in cotton-wool and flannel. The ligature was kept on for two hours and a quarter, the patient being under chloroform. Before removing the ligature a compressor was applied to the femoral above it with a few readjustments (during which digital compression was kept up) and retained there for seven hours. On removing the tourniquet pulsation returned in the tumour, which, however, was smaller, felt more solid, and on auscultation communicated a less rough bruit to the ear. After this date compression was kept up by the patient himself. This was effected either by a (5 lb.) shot bag, by Signoroni's tourniquet, or

by the fingers, the methods being varied according to the patient's inclination. After a week of this treatment the aneurism became smaller and more solid and its impulse less heaving. The œdema of the leg subsided and the patient was free from pain. Compression was now supplemented by genuflexion at night, the leg being now capable of being bent to such an angle as to arrest pulsation in the tumour.

On Sept. 25th the aneurism seemed almost cured, pulsation being at times scarcely perceptible. The collateral circulation was well established. The articular arteries could be distinctly felt pulsating.

On Nov. 17th, on consultation with Messrs. Cross and Ticehurst, it was decided to tie the artery, prolonged compression having failed to effect a cure. This Dr. Leachman did on the 20th. The patient being under ether the femoral was tied at the apex of Scarpa's triangle with carbolic catgut, the wound sponged with carbolic lotion, and the edges brought together with silver wire sutures. No other antiseptic precautions were adopted. After the operation the temperature rose above the normal on one occasion only; otherwise it remained subnormal for some days. Slight pulsation was felt in the aneurism on the 25th; but it gradually ceased, and on the 30th the wound was healed without any previous suppuration.

On Jan. 6th, 1883, the patient was discharged well, and went to work.

Remarks by Dr. LEACHMAN.—In this case compression was continued for an unusually long period. Successful cases of even more lengthened compression (eight months), quoted by Holmes, seemed, however, to warrant a prolonged trial of this treatment before subjecting the patient to the risks of Hunter's operation; and I believe that the long-continued compression, by giving time for the thorough establishment of the collateral circulation, reduced to a minimum the principal danger of the operation—gangrene. The rapid healing of the wound without suppuration in the absence of antiseptic precautions is also noteworthy.

GUY'S HOSPITAL LYING-IN CHARITY.

CASE OF DOUBLE CONGENITAL HYDROCELE; SUPPURATION; DEATH.

For the following notes we are indebted to Mr. H. Poole Berry, M.R.C.S., senior resident obstetric assistant.

B. M.—, a primipara, had been in labour thirty-six hours, and had become exhausted. On the evening of March 2nd bow-forceps were applied by Mr. H. T. Sells, the junior resident obstetric assistant. She was then quickly delivered of a well-developed male child. Nothing unusual was observed in the condition of the child's scrotum. On March 10th the mother died of exhaustion, following an attack of puerperal mania. On the same day the attention of Mr. Miller (extern obstetric attendant) was drawn to the condition of the scrotum of the child, which was red and swollen. Hot fomentations were applied. On the following day, at noon, the child, then nine days old, was brought to the hospital. It was stated that it had not passed any urine since 5 A.M. on the previous day. The whole of the scrotum was much swollen, red, glistening, and somewhat tense. The possibility of extravasation of urine at once presented itself; but the fact of the inflammation being strictly confined to the scrotum, neither the penis, perineum, nor abdomen being in the least degree affected, seemed strongly to negative this view. As phimosis existed the prepuce was stretched with dressing forceps, and poultices were ordered to be applied over the pubes. In-

structions were given to the nurse that the child should be brought to the hospital again in the evening if no urine had passed. At 9.30 p.m. the child was again brought, in much the same condition, but looking pinched and ill. It had been very fretful, but was now quieter. The inflammation was strictly limited as before, but was more intense in character, the whole scrotum looking more angry, giving the impression that sloughing might soon supervene. A No. 1 gum-elastic catheter was passed, and about two drachms of urine were drawn off. The child was taken home, and about ten minutes afterwards died.

A post-mortem examination was granted by the father, and was made the following afternoon (March 12th). The bladder was found to be empty, and the urethra normal. On cutting into the scrotum nothing abnormal was noticed until the serous membrane, on the left side, was incised, when pus freely escaped. In this cavity the testicle lay bare, and from it a probe passed freely into the peritoneal cavity. The peritoneal opening was distinctly perceptible to the finger, examining through an incision made through the abdominal wall, but was not sufficiently patent to admit its tip. The same condition existed on the right side. There was no diffuse peritonitis existing, though possibly some early peritonitis may have been present around the immediate neighborhood of the rings. This was not certainly ascertained, as small an incision as possible having been purposely made into the abdominal cavity.

Remarks.—It seems possible that in somewhat analogous cases, where no post-mortem has been made, a similar condition may have existed, and that death may have been assigned to erysipelas, or to some other more or less superficial inflammation of the scrotum, the ante-mortem appearances in this case being certainly to some extent calculated to support such a view. A somewhat similar case has occurred recently at this hospital in which the inflammation being not so strictly limited, the idea of extravasation of urine was entertained, when, post mortem, a condition similar to that just described was found to exist.

SHEPPEY UNION INFIRMARY.

CASE OF ATTEMPTED SUICIDE BY CUTTING THE THROAT; ASPHYXIAL ATTACK; RECOVERY; REMARKS.

(Under the care of Mr. GEORGE BLAND.)

On January 17th last a negro named B— was discovered almost insensible in a garret in his house at Sheerness, with a large gash across his throat, and his wife, a white woman, in a room downstairs partly burnt, with her head and face battered about, and her windpipe, right common carotid artery, and internal jugular vein completely severed. Her son, by a former husband, stated B— had attacked him also and inflicted several wounds, one penetrating the upper and anterior part of the left lung. He was seen by Dr. Arrol, who recommended his removal and accompanied him to the infirmary.

On admission he was in a state of extreme prostration. A large wound extended across the throat, higher and deeper on the left than on the right side. It severed the larynx, slicing off the anterior part of the cricoid cartilage and lower portion of the left side of the thyroid, penetrating backwards into the pharynx. The edges of the opening into the latter were much retracted, and would easily have permitted the passage of a good-sized plum. Hæmorrhage having ceased, stimulants and nourishment were administered by

means of the stomach-pump. There was some difficulty at first in introducing the tube, for, owing to the altered position of the parts, the point of it impinged on the severed edges of the œsophagus. This was overcome by introducing the finger into the pharynx through the wound, feeling through the top of the œsophagus and so guiding the tube into it. The finger could readily be passed behind the thyroid cartilage and under the tip of the epiglottis, which could be distinctly felt flapping up and down, sometimes even it could be seen when the head was thrown well backwards and one looked up into the wound. After a couple of days the secretions increased greatly, large quantities of glairy ropy mucus and saliva giving considerable trouble. So tough was this mixture that it had to be extracted by winding it round the head of a small mop like a cable round a windlass. No air entered the mouth, breathing being carried on through the external wound. The hyoid bone, thyroid cartilage, etc., were drawn up beneath the root of the tongue, causing the wound to gape immensely.

On Jan. 19th, about ten minutes after the patient had been fed, his head fell forward and he became convulsed and gasped. Mr. Bland was standing a few yards off, and as he got to B—'s side he gave another struggle and an abortive gasp or two, a look of intense agony passing over his face, after which he collapsed and lay back apparently dead. No pulse could be detected at the wrist. As a forlorn hope, Mr. Bland threw back the man's head and passed the tip of a finger into the windpipe, pressing outwards, while with the other hand he pressed the ribs, as in artificial respiration. A very faint attempt at inspiration followed. A teaspoon being close at hand, the handle was inserted into the trachea, and the breathing began to improve, though still very slow and faint. A couple of hairpins were bent to a right angle, passed one at either side of the trachea, and used as retractors. In two or three minutes breathing was re-established. The severed cricoid cartilage had collapsed, while the divided edge of the left cricothyroid muscle got tilted over and acted as a valve. This was subsequently snipped off.

Nothing particular occurred for some days, when Mr. Bland was hurriedly summoned to the patient. He was breathing with great difficulty, a large quantity of mucus having got into the air-passages was gurgling to the top of the trachea at each expiration and then being sucked down again. The opening was too large to favor its expulsion. The insertion of a tracheotomy tube at once had the desired effect, the constriction of the opening concentrated the expulsive force, just as a choke-bore gun barrel does, and he shot out an immense quantity of stuff through the tube, upon extracting which the trachea was found quite clear. An important point in treatment had now to be decided upon. The wound in the laryngo-pharyngeal septum was still very large, and presented no prospect of closing—that is to say, though the edges appeared to be healing a large opening would remain; in short, it would heal as a pierced ear does. For all practical purposes the larynx was destroyed, and even were it possible for it partially to unite in front, the epiglottis as a safeguard would be next to useless, as air and mucus, and perhaps food eventually, would come down the pharynx and enter the trachea through the fistula already described. Besides this, inside the wound there was great cedema, large portions of mucous membrane being raised up and looking, and feeling to the touch, like hæmorrhoids. It was decided to retain the tube and not permit the external wound to heal, for it was felt had this been attempted, asphyxia, either instantaneous or gradual, would

result before long. After about a month the man was able to swallow solid food perfectly and liquids partially. Even at this length of time it was easy to see a piece of bread pass down; it would stop for a moment at the fistula, and then suddenly disappear.

Remarks by Mr. BLAND.—This is a good example of the chief dangers in cases of cut-throat after the first shock is over. These are chiefly due to oedema and mucus trickling into the trachea, slowly asphyxiating an exhausted patient. Should difficulty of breathing arise from the former, I do not think there can be any second opinion as to propriety of performing tracheotomy; let the second be overcome, and scarcely any case need be regarded as hopeless, no matter how severe it may appear at first, provided the surgeon is prepared to give it plenty of attention. He must visit it frequently, and administer food and stimulants with the stomach-pump two or three times daily, seeing at every visit the wound is kept clean. As no two wounds are exactly alike, the detailed treatment of each must be regulated by circumstances, but I think it may be safely laid down that the old plan, not to sew up a penetrating wound, is perfectly sound, and that this plan of treatment may be carried further, especially in the early stages, and no attempt made to close the wound by keeping the head forward. The shock causes partial paralysis of the muscles of the throat, which is not recovered from for several days, and may permit the entrance of mucus into the passages. Food can only get there by neglect, as the use of the stomach-pump can always prevent this. Enemata will probably have to be frequently administered. In the above case so sluggish were the bowels that he never had a motion for over a month without one. Attention, of course, must be paid to the general treatment; but I think the chief points have been already indicated. Five weeks after the injury the external wound was somewhat larger in area than a shilling, while the opening in the laryngo-pharyngeal septum still existed. On Feb. 24th he was committed for trial, and I accompanied him to Maidstone gaol, handing him over to the charge of the prison surgeon. The tracheotomy tube was still in use, as I had not modified my opinion as to the propriety of not permitting the external wound to close. Most probably we shall hear of him again, as, in the event of his being convicted and sentenced to death, the question must arise as to the humanity of executing a man in his condition.

CARDIFF INFIRMARY.

VERTICAL DISLOCATION OF PATELLA.

(Under the care of Dr. VACHELL.)

For the following notes we are indebted to Mr. P. Rhys Griffiths, M.B., B.S. Lond., house-surgeon:—

Michael E—, aged thirty-one, a laborer of strong build, was admitted into the infirmary on the night of Feb. 13th, 1883. He said that when assisting some men to push a trolley his legs were jammed between the trolley and a long iron bar called "The David." The pain he experienced was intense—he described it as "wrenching." After the accident he was unable to move.

On examination the left leg was found to be fully and forcibly extended, and the dislocation of the patella was evident. The patella had been rotated on its vertical axis, the convex anterior surface was directed forwards, inwards, and slightly upwards. The outer slightly concave half of the posterior surface of the patella was plainly seen and easily

felt, the skin being very tense. The right border of the patella rested apparently in the small depression immediately above the inter-condylar groove. To the inner side of this border immediately there was a well-marked depression, in which the ridge to the inner side of the articular surface of the internal condyle of the femur, as well as a part of the smooth condylar surface, could be felt; a portion of the external condylar surface was also felt. The tendon of the quadriceps extensor was very tense, and could be plainly seen as two strong bands. The patella was slightly movable on the right border as axis. Attempted flexion of the limb was accompanied by acute pain. The patient complained of pain only over the inner side of the knee-joint.

The patient was put under the influence of ether, and as soon as the quadriceps muscle relaxed, with a very little lateral pressure on the margins of the bone the dislocation was easily reduced by Dr. Vachell.

Remarks—This is about the twentieth case which has been placed on record. As a rule, these dislocations are caused by muscular spasm; in this case there can be no doubt that it was caused by the pressure of the iron bar directly upon the patella itself, the spasm of the quadriceps retaining it in its abnormal position. The reduction, which in many cases has been most difficult, was in this very easily effected. After the reduction a back splint was put on, and this on the following morning was replaced by a plaster case.

EYE INFIRMARY, GLASGOW.

REMOVAL OF EYELASH FROM ANTERIOR CHAMBER FOUR WEEKS AFTER INJURY, RESULTING IN GOOD VISION.

(Under the care of Dr. CRAWFORD RENTON.)

J. D—, aged thirty, gamekeeper, was admitted on Oct. 18th, 1881. He was suffering from an injury to his right eye, caused by the splintering of a percussion-cap two weeks previously. On examination, a slight abrasion of the cornea was observed; the iris was irregular, and across the lower and inner side of the pupil a minute foreign body seemed to be lying, but owing to the presence of iritis, it was difficult to be certain that it was not pigment or lymph. Fomentations and atropine solutions were recommended to soothe the pain and subdue the iritis. On Oct. 28th the eye was quiet, the pupil had yielded, and it was now more apparent that a foreign body was present, and that it was either a very fine splinter of the cap, or, as the resident surgeon, Dr. Hunter, suggested, an eyelash.

On Nov. 2nd Dr. Renton made an incision through the lower and outer aspect of the cornea, and removed with a fine pair of forceps the foreign body, which proved to be an eyelash.—18th: Pupil did not yield freely after the operation, but it gradually improved, and the patient was dismissed with good vision.

Jan. 6th, 1883.—The patient is reported as having found his eye as useful as formerly during the whole shooting season, and no trace is left of the inflammatory attack or ill effects from the injury.

INSPECTOR GEN. ALEX. DAVIDSON, M.D., who died at Cheltenham on March 31st, was one of the oldest members of the Royal College of Surgeons. He was born in 1796, and was admitted a member of the College in September, 1818. He entered the East India Company's Service as assistant-surgeon in 1819, and had seen a great deal of active service.

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Occlusion of Vessels by Oil.—Adeno-Sarcoma of Testicle and Abdominal Viscera.—Sarcomatous Ulcers of Back.—Hypertrophy of Limbs.

THE ordinary meeting of this Society was held April 17th, Mr. Arthur Durham, Vice-President, in the chair. The material which the Society had to deal with was greatly in excess of the time at its disposal. Many card specimens of interest were exhibited. The chief part of the evening was taken up with the reading and discussion of some cases of tumours of doubtful affinities.

Dr. Wilks introduced Dr. Handfield Jones with the view of permitting the latter gentleman to bring forward some interesting microscopic specimens which seemed to show that the smaller cerebral vessels might become blocked by globules of oil as the result of atheroma of the larger. The patient was a man, aged forty-eight, who had been under the care of Dr. Broadbent at St. Mary's Hospital. He had suffered for some time from mental aberration, of which restlessness and excitement were the chief features. In former years the man had drunk a great deal. The urine contained about one-third of albumen, and there was general oedema. At the autopsy the heart was found to be hypertrophied, and weighed twenty-five ounces; there was no valvular mischief; the pleurae and peritoneum contained an excess of fluid; the liver was enlarged; the kidneys weighed seven ounces and a half, were slightly granular on the surface, and were well pronounced examples of morbus Brightii. Examination of the vessels showed that the large basal arteries were the seat of atheromatous changes. In the small vessels about two or three removes from the capillaries oil drops, plugging the lumina of the arteries, were to be seen. Sometimes these oil drops existed alone, at others they were associated with fatty molecular matter. The oil plugs were spherical or cylindrical, with rounded ends; sometimes elongated and pyriform. The oleaginous masses seemed to be inside the vessel, and blocked the whole channel; some were of great length, as much as one-nineteenth of an inch. In many specimens some blood-clot was entangled and mixed with the oily material. The question necessarily arose, whether these globules of oil originated *in loco*, or were transferred from the more proximal branches of the artery affected. Where the plug of oil existed without any molecular matter either in the vessel or its wall, it was probable that it had originated at a distance, and was of the nature of an embolus; otherwise it was legitimate to regard the material causing occlusion as having developed at the site affected. The material was regarded as of an oleaginous nature, because of its general appearance and its association with atheroma of the large arteries, and because it for the most part gave a black coloration when treated for a long time with osmic acid. The plugs showed some preference for projecting angles of the affected vessels. The atheromatous process was regarded as a primary fatty degeneration: no inflammatory exudation cells could be detected. Ziegler had described fatty changes in the cells forming the capillary wall occurring in the first place close to the nuclei, and which led to the narrowing of the capillary channel. Cornil and Ranvier made no mention of such changes as Dr. Handfield Jones described. Four other cases had since been examined, and the conclusion was ar-

rived at that marked atheroma of the larger vessels might be detected without any accompanying change in the capillaries. Drawings illustrating the microscopical appearances, as well as the actual sections, were exhibited.—Dr. Wilks thought the specimens of sufficient importance to demand the benefit of a report by a special committee. To this the meeting and Dr. Handfield Jones assented.—Dr. Cavafy inquired whether the serum had been examined; if it had been found to be milky, this condition of lipemia would tend to throw light on the nature of the vascular plugs. The blood had, however, not been specially investigated.

Mr. Victor Horsley showed a specimen of Cystic Sarcoma of the Testicle, with secondary growths in the other viscera. The case was also of interest from the association of many congenital defects of structure. The man was a spare built individual, aged thirty-one, height about five feet four inches; the foramen ovale was widely patent, measuring an inch and a quarter at its longest diameter; it was divided by a median trabecula. No trace of a Thebesian valve could be found; there was partial atresia of the pulmonary orifice, and the segments of the pulmonary valve were adherent and formed a fibrous cone; the tricuspid valve and chordæ tendinæ were thickened and puckered. The right testicle was ill-developed, the kidneys and spleen were unusually lobulated, and there was a congenital inguinal hernia. Eighteen months ago the patient was kicked in the left testicle; the growth of the tumour followed at a short interval. On admission into the hospital, a rough systolic murmur, loudest at the third left cartilage, was heard, and a very remarkable venous pulse was noted, the pulsation extended down to the veins at the elbows. In the neck a powerful double pulsation was detected, which consisted of two series of alternating beats; one was synchronous with the radial pulse, the other was a little before it. Tracings were taken of this mixed carotid and jugular pulsation by Marey's tambour; the respiratory rhythm was traced by Burdon-Sanderson's stethograph. It was demonstrated, apparently without flaw, that the second pulsation was synchronous with, and probably due to, the auricular systole. It was certainly too late to be an exaggerated diastolic wave. Its rhythm proved that it was independent of respiration. The diseased testis measured 3 in. by 1½ in.; the tunica albuginea was thickened; the body was riddled with small cavities; the stroma was enlarged, and was seen under the microscope to be made up of fibrous tissue and masses of sarcomatous tissue. Round cells, varying in size from a red disc to a leucocyte, were seen, and many hemorrhages had occurred both into the cysts and into the solid structure. The smaller cysts were lined with columnar epithelium, the larger with flattened cells; much mucin was also present. Masses of secondary nodules riddled the liver in every direction; there were a few in the lungs. But none of the visceral nodules presented a cystic structure; they were merely sarcomatous. Extravasations were seen in the hepatic growths. The only other nodule was seen in the left side of the wall of the bladder. The venous radicles and lymphatics were free from disease. The injury was probably the exciting cause of the tumour of the testis; the other new growths probably developed in the various parts as the result of a defective state of the general health. Mr. Horsley was inclined to think that his case lent some support to the doctrines of Cohnheim and Leopold—viz., that residues of embryonic tissue were the probable foci of development of the various tumours; this view was believed to receive some confirmation from the fact that numerous congenital defects were present in the case narrated.—Mr.

Butlin said that as far as he had understood, Mr. Horsley wished to ascribe the tumour of the testis, and all the secondary growths, to the injury which the man had received eighteen months previously. He could not agree with the suggestion that the case supported the teachings of Cohnheim. He might see some reason for associating the new growths with the congenital defects if the former had occurred at or near the site of the latter. He was disposed to regard the sarcocele as one of lympho-sarcoma with cysts which probably originated from the tubuli seminiferi. It was an extraordinary circumstance that such tumours of the testicle gave rise to no secondary affection of the lymphatics.—Mr. Victor Horsley, in reply, said the kick was merely regarded as determining the growth of the testicle. The amount of small-celled growth was small compared with that of the fibrous tissue, and there was very little reticulum; for these reasons he did not consider the case one of lympho-sarcoma. The growths in the liver and lungs were detected during life after the removal of the testis; their progress of growth was watched over the six weeks which elapsed before death.

Mr. Davies Colley showed specimens removed from a single woman, a cook, aged twenty-nine, who in September, 1881, came under his care. The family history was good, there was no history of syphilis, the previous health was faultless. Eighteen months previously two small tumours the size of walnuts appeared on either side of the lumbar spine. These were treated, and disappeared; six months ago a tumour grew from the left gluteal region and one from the right lumbar region, the former increased without pain, and at the time of admission into Guy's Hospital measured four or five inches across. It had ulcerated; its upper border had a crescentic shape, the lower border was elevated, and the neighboring skin was of a livid-red color. It thus seemed to be spreading at one part and healing at the other, very much like a severe tertiary syphilitic ulceration. The lumbar tumour had a bossed outline; measured five inches across each way and was raised about an inch; the surface was smooth and glazed. Iodide of potassium and mercurials gave no improvement. The general health began to suffer, and the patient died from exhaustion in November, 1881. Shortly before her death a similar tumour appeared in another part of the left gluteal region above the old ulcer. The post-mortem examination was made by Dr. Goodhart, who detected an infiltrating soft fleshy growth spreading into the subcutaneous tissue of the growing edge of the ulcer; this tissue on section showed yellow tawny colored areas, and was sharply defined towards the neighboring connective tissue. Both psoas muscles were affected. The third lumbar vertebra was softened, but no deposit of cheesy matter was seen. The microscopical appearances of all the growths were similar. There was a delicate misty-looking reticulum of connective tissue, enclosing large numbers of round nucleated cells like leucocytes, and some small colored masses like myeloid cells. There was no appearance as of the conversion of round into fusiform cells as occurs in gummata. There were no tubercles in the internal viscera. The sharp definition of the tumour was different from ordinary lympho-sarcoma. It was certainly difficult to exclude the diagnosis of mere chronic inflammatory growth.

Dr. Frederick Taylor read a somewhat similar case. The man, a gardener, aged forty-two years, first came under treatment for symptoms of nervous origin; there was no history of syphilis or gonorrhoea. The previous history was good, except for the occurrence of small-pox some years

before. The nervous symptoms had been present for six weeks only. A patch of unilateral alopecia was observed six months before. There was staggering gait, tremor of hands, and difficulty of speech, probably due to a disordered action of the tongue. Under the use of iodide and mercury the nervous symptoms improved. In October two swellings appeared, one on the inside of the right knee and the other on the back. These swellings increased in size, so that the one on the back measured five inches by four in December. There was partial ulceration with scabbing on both tumours. The one on the lower extremity gradually subsided. The tumour on the back began to slough, and assumed a greenish appearance mixed with pale pink areas of granulations. Mr. Durham then saw the case, and advised calomel and vapor baths. Iodide of potassium had been given without effect; it was even thought that the eruption might have been due to this drug. At Christmas, 1882, fresh lesions appeared; numerous oval, red, thick, raised patches of erythema appeared nearly all over the cutaneous surface. Some of those on the legs began to slough, others ulcerated and formed scabs, whilst others subsided. The large tumour on the back also further sloughed, and left a broad area of granulations. A hard, firm, swelling, the size of a Barcelona nut, appeared on the front of the chest, and looked like a sebaceous tumour; this spontaneously disappeared. In January, pyrexia, albuminuria, and oedema of the legs set in, followed by laryngitis and death from oedema of the lungs in February. At the autopsy the skull was found thickened, the pericranium red and thick in two places, each the size of a shilling, the larynx was ulcerated, and the cartilage was laid bare; there were the signs of acute pericarditis; also large white kidneys. Many of the cutaneous tumours were like boils on section, others were seen to be in various states of sloughing. The epididymis was quite smooth and densely white, as if in a condition of chronic inflammation. The border between the tissues of the tumours and the surrounding structures was ill-defined, the small round cells of the growth infiltrated the intervals between the nerve and muscle fibres in the neighborhood. Syphilis was naturally thought to be the cause of these appearances during life, but no trace of a gummatous tumour was to be found; the body of the testis was normal; there were no signs of tubercle. The rapid course and extensive distribution of the disease were remarkable.—Mr. Durham was very much struck with these cases; they were of a non-descript type, and might be regarded as forming a group of tumours intermediate between inflammatory new formations and genuine tumours. He mentioned an anomalous case which happened in a young woman; the cervical glands became enlarged and ulcerated, the surrounding subcutaneous tissues were infiltrated, ulceration and sloughing extended, and the patient died. At the autopsy glandular enlargements were found in the abdomen. Another case was instanced; this occurred in a man, aged fifty-six years. A pimple formed on the right leg, ulcerated and scabbed, and finally fell off; a little tumour, however, appeared at the same place, and gradually developed, and subsequently a number of small tumours arose in various parts—legs, ankles, and arms. The tumours increased in size, some became confluent, others remained isolated; ulceration occurred in some, in others sloughing. The patient died. No visceral complication was found. No important glandular enlargements were detected.

Mr. Pye Smith narrated the case of a man who presented a series of Small Tumours, which at their first appearance looked like purpura, but

ultimately took on the character of sarcomata; they affected the skin and subcutaneous tissues, and seemed to be secondary to a tumour of the colon. Dr. Hilton Fagge had collected a number of such cases, and had contributed a valuable article in the *Guy's Hospital Reports*.—Dr. Stephen Mackenzie remembered a case under the care of Dr. Andrew Clark, fourteen years ago, in which masses of glandular tissue had developed and become ulcerated in the front of the chest; this was regarded as an example of lymphadenoma. A second instance occurred in a patient the subject of anæmia with retinal hæmorrhages; there were hundreds of tumours all over the body, varying in size from a pea or nut to a Tangerine orange; there were typical lymphomata. The viscera also showed similar changes. In this case there was no ulceration, though it was reasonable to suppose that ulceration might have set in had the patient lived.—Mr. Bendall mentioned a remarkable case of disseminated tumours which Mr. John Clay, of Birmingham, had published in *THE LANCET* last year. The patient had several attacks of erysipelas. The tumours affected only the cutis vera, and infiltrated the neighboring tissues.—Mr. Butlin said that the tumours under discussion ought probably to be given a place to themselves. They were between infective tumours and ordinary new growths. He suggested the possibility of the dependence of lympho-sarcomata and other new growths on the presence and development of micro-organisms.

Mr. Eve showed specimens of Congenital Hypertrophy of Limbs. The foot was affected in a girl, aged twenty-four years. The skin of the sole was enormously thickened, and although there was general hypertrophy, the plantar integument was enlarged out of proportion to the other tissues. In this case there was also an asymmetrical enlargement of the left side of the head, which showed itself also in the brain and tongue. The limb had been noticed to be enlarged from birth, but a rapid increase had occurred during the last seven months. Another specimen was from a man aged thirty-four years. The enlargement of the hand was seen at birth; but only a year before admission to the hospital the extremity began to increase much more rapidly. The lymphatic channels and spaces were enlarged. This was not, however, regarded in the light of a casual connection. Altogether, forty-six such cases had been recorded. Mr. Eve mentioned what he believed to be a unique case; there was no enlargement at birth; the whole hypertrophy had developed in four months. In those cases in which there was a congenital history, the tumours tended to be similar to dermoid cysts in their nature, whilst in the rarer kind the tumours agreed with the new growths which developed in later life. In one instance fatty tumours, fibroid tumour of the parotid, fibrous epulis of lower jaw, osseous outgrowth of the patella six inches and a half long, exostosis of the os calcis and first metatarsal bone, all in the left side, were associated with hypertrophy of a limb. These congenital hypertrophies were liable to a peculiar form of ulceration, not epitheliomatous.

Dr. Lediard, of Carlisle, showed two card specimens: (1) Dry Caries of Knee-joint; (2) Melanotic Spindle-celled Sarcoma and Gland. Dr. Taylor showed a card specimen of Intestinal Obstruction resulting from adhesion of the ileum to the mesentery. Dr. Savage showed, for Dr. Strahan, of Northampton, Symmetrical Tumours of the Dura Mater, and Atrophy of one Lateral Lobe of the Cerebellum. Mr. Watson Cheyne demonstrated some Tubercle Bacilli. Dr. Abercrombie exhibited a Heart showing complete atresia of the right ventricle. A Cancer of the Pancreas, with sec-

ondary affection of nearly all the viscera, was exhibited by Dr. Percy Kidd. Two recent specimens were also shown: (1) a Syphilitic Intestine, by Mr. Victor Horsley; (2) Laryngeal Phthisis, by Dr. Morison.

The ordinary meeting of this Society was held on Tuesday, May 1st, Mr. J. W. Hulke, President, in the chair. The discussion on diabetes was concluded. Dr. Dickinson and Dr. F. Taylor showed a large number of microscopical specimens of organs from diabetic patients, and the President intimated that, in accordance with the wish of Dr. Dickinson, a committee would be appointed to examine and report upon these, and other similar preparations.

Mr. R. J. Godlee read the report of the Morbid Growths' Committee on Mr. Clutton's specimen of Tumour of the Scalp, in which Mr. Clutton's view that it was an Alveola Sarcoma was corroborated.

Discussion on Diabetes.

Dr. Seymour Taylor remarked that he had recently had opportunities of making or witnessing the post-mortem dissections of four cases of diabetes. All four were typical, and in each the usual form of coma supervened shortly before death. He examined the kidneys carefully of three of the cases, not with any idea of finding a primary lesion, but with a view to ascertain if there were any, and, if so, what secondary changes. These organs presented to the naked eye the usually described vascular engorgement. Microscopically the glomeruli showed marked extravasation of blood, hence they were of a pale-yellowish tint. The epithelium of the tubules, however, was remarkable. The cells were large, of a yellow-brown color, and their nuclei failed to take the logwood stain. The most characteristic feature was the tendency for the epithelium to come away from its basement membrane *en masse*, so that in parts the kidney presented a mere skeleton outline of its normal condition. This shedding of epithelium was not in the form of a cast, as there seemed to be no fibrinous exudation to form the basis of a cast; it was merely a well-marked necrosis, and as such was entirely a secondary change. Dr. Taylor could corroborate Professor Frerichs' observations as to the method of staining diabetic kidney sections by means of a weak solution of iodine, which acts upon the glycogen; in order to obtain good results, it was necessary to harden the organ in absolute alcohol, and not in an aqueous solution. The liver presented a similar congested state, the cells being atrophied from pressure of exuded blood. As regards the central nervous system, the positive evidence of structural change was almost nil. Dr. Taylor observed he could find no morbid change in the brain, the medulla, the spinal cord, or in the sympathetic ganglia, with the exception of the hyaloid thickening of blood-vessels, noted by Dr. Stephen Mackenzie. Some of the sections exhibited bore a great resemblance to the so-called changes in chorea; but he thought he had seen similar conditions in brains and spinal cords which were considered healthy. He was sceptical of some of the so-called lesions of nervous system, and was inclined to think that many appearances we regard as morbid might be due to our method of preparation and of cutting. Since Bernard's remarkable discovery as to the production of glycosuria by injury to the fourth ventricle we seem to have been working with this observation as a centre. We have taken a physiological experiment as the basis of a supposed pathological fact. He looked upon the disease with our present light as a functional one.

Mr. Victor Horsley had examined the medulla oblongata in three cases of so-called typical diabetes mellitus, each case dying comatose. In none was any morbid condition to be found, save congestion (no hemorrhage). In one of these cases the liver and kidney showed well-marked cloudy swelling. The secondary importance of this condition is proved by late experiments in which glucose injected into the system (rabbits were the animals employed) caused cloudy swelling and disintegration of the renal epithelium. In view of the extreme variation among the results of research into the morbid anatomy of diabetes, it was suggested that no distinct disease existed, but that abeyance of function, acting not only centrally but peripherally, would bring about the symptoms supposed to indicate a special disease.

Dr. Frederick Taylor had paid attention chiefly to two points in connection with diabetes—the morbid anatomy of the nervous system and the fatal termination of the disease. He had, some years ago, in conjunction with Dr. Goodhart, published the results of an examination of the central nervous system in nine cases of diabetes, and they were unable to find in them the morbid changes described by Dr. Dickinson. Dr. Taylor now exhibited a number of the specimens for the judgment of members of the Society. He considered the majority of the specimens were practically healthy, and only one case showed anything that deviated much from the usual standard; and he thought that no constant change had been found as the initial lesion of diabetes, and that the account of degeneration and decay of the nervous system was not justified by what had hitherto been seen. Unusual thickness of the walls of the vessels and large size of the vessels might be part of a general condition; a large central canal was to be otherwise explained than by vascular engorgement, and was not peculiar to diabetes; while the condition called milary degeneration was certainly the result of reagents. Dr. Taylor had not seen varicose dilatation of vessels in his specimens, nor evidence of degeneration of the nervous tissue. There remained the presence of orange semi-crystalline bodies about the vessels, and in the perivascular spaces, which were abundant in one of his cases; but he considered it still unproven that they indicated a congestive state of the nervous system which could be regarded as the cause of the disease. Recently he had examined four other cases, and though two were much spoiled in hardening, it was quite clear that they had not undergone any such degenerative changes as were described. Dr. Taylor next referred to the mode of death in diabetes, and pointed out that the proportion of fatal cases which occurred in consequence of the curious group of symptoms called “diabetic coma” was a very large one; of 53 cases dying within the last ten years at Guy’s Hospital, 33 died comatose; and in 17 of these there was no lesion of the viscera; while in 3 the lesions were inactive and could not have contributed to the result; and in 10 the coma supervened in the course of pneumonia or phthisis. He found evidence that neither the theory of fat embolism, nor that of acetone in the blood satisfied all cases; and he referred to the frequency of severe abdominal pain as an early symptom—an important fact, as it might give rise to a diagnosis of perforation or peritonitis.—Dr. Taylor also exhibited Microscopic Sections of the Pancreas from a case of diabetes, which was almost entirely converted into fat. It was on record that the pancreas had occasionally been found atrophied or otherwise altered in diabetes. At Guy’s Hospital some alteration had been noticed in five cases during the last ten years. Twice it was merely described

as small or wasted; three times, including the case exhibited, it was fatty.

Dr. Dawson Williams had examined the registers at University College Hospital for ten years, but the number of fatal cases of diabetes available for report was small. He referred to a group of six cases, occurring in young people, which had certain symptoms in common. Well-marked coma, accompanied in four cases with extreme dyspnoea, was the immediate antecedent of death in five of the cases. In three of the cases there was some phthisis pulmonalis present, but in none was any distinct evidence of tubercular disease found elsewhere. In two cases albuminuria was a constant symptom during the whole time the patients were under observation. No constant post-mortem appearances had been recorded; in two cases the puncta cruenta were stated to be more numerous and prominent than natural; in one case the perivascular spaces were said to have been enlarged; in one some swelling at the tip of the calamus scriptorius and congestion of the membranes in the neighborhood were noticed. It was thought that an examination of the Registrar-General’s Returns favored the idea that diabetes was becoming a more common disease. Thus the number of deaths registered as due from diabetes had risen from 537 in 1862 to 1,059 in 1880, an increase of 49 per cent., while the increase in the total number of deaths from all causes was only about 20 per cent.; again the death-rate from diabetes was 24 per million in 1850, and 41 per million in 1880; whereas the death-rate from “all causes” was almost the same (it was, in fact, a little lower in 1880 than in 1850.) The number of deaths from diabetes, compared with the total number of deaths, had also advanced about 30 per cent. The table published by Dr. Dickinson in his work on “Diabetes,” which showed the number of deaths from this disease at each decade of life during the decennial period 1861 to 1870 was exhibited graphically, and compared with a similar chart which had been prepared from the Registrar-General’s returns for 1871 to 1880. It resulted from this comparison that the incidence of diabetes at the various ages had not materially differed in the two decennial periods. It was greatest in the decade of years between the ages of fifty-five and sixty-five in both sexes, but the preponderance in this decade was much more marked in men than in women; this difference between the sexes, however, was less marked in the second decennial period than in the first. How far the relative greater mortality among women in the decade of years between twenty-five and thirty-five was due to any connection between diabetes and childbirth, such as Dr. Matthews Duncan had suggested, there was no evidence to show; indeed only six cases of diabetes had been registered in ten years in women dying within one month after childbirth.

Dr. Dickinson asserted that diabetes must have a pathology, and depend upon some change in the permanent structures of the body. In addition to his other investigations, he had recently examined organs from four cases of diabetes for the purposes of the discussion, and the results obtained went far to corroborate those previously arrived at. In his earliest observations he had not sufficiently allowed for natural variations in the cavities and channels of the brain, and this had led to doubt being cast more widely than deserved upon all his results. The brain, though at first appearing healthy, was hard in texture, injected, and occasionally showed surface hemorrhages. The centrum ovale showed a cribriform appearance, which, however, was also seen in chronic insanity. The microscope revealed:—1. Dilatation of the blood-

vessels. 2. Small extravasations of blood. 3. Dilatation of perivascular spaces. 4. Alteration in the perivascular sheaths and nervous matter bounding the cavities. Of fifteen diabetic brains he had found extravasations of blood in seven. Perivascular changes—thickening of the sheath, erosion or degeneration of the nervous matter—were invariably found; these were most marked around the largest vessels. The cavities were often sprinkled with grains of blood pigment. The changes in the cord were slight: erosion and commencing degeneration of the grey cornua. A careful examination of the sympathetic system in all its parts had shown him that it was usually healthy. He had once seen granular degeneration of the cells of the cervical ganglia, and in another case a less degree of the same change in the semilunar ganglion. Lungs showed caseating pneumonia, followed by cavities. The liver exhibited marked general congestion; a peculiar dilatation of the capillaries, possibly from a post-mortem development of gas, he had seen in two cases. In the kidney he had found evidence of tubal and interstitial nephritis. He thought the brain must be regarded as the primary seat of the disease. This he had always found diseased, with signs of an altered relation between the bloodvessels and the brain tissue; but these changes were not constant in position, and often widely scattered. The changes were not peculiar to diabetes, though constant with it. Against the view that the disease began in the blood and affected the brain secondarily was the fact that it often came on as the consequence of a mental impression or cerebral state, as grief or anxiety.

Dr. Pavy addressed himself to the condition of the blood, which he believed to be at the bottom of diabetes. He was sure the primary lesion was a chemical fault. He had recently been performing many chemical investigations of great importance in this matter. There was a distinct group of carbohydrates, moved by means of ferments. Thus starch acted upon by diastase, saliva, or pancreatic juice was converted first into a dextrin, then into maltose, attended with increased hydration and increased cupric oxide reducing power. Starch was $C_{12}H_{20}O_{10}$; maltose was $C_{12}H_{22}O_{11}$. The dextrins intervened in composition. Starch had no cupric oxide reducing power and it was precipitable by alcohol. Dextrin was no longer preceptible by alcohol, and could reduce cupric oxide at first a little, gradually more and more up to maltose, three times that of the first dextrin; and glucose had still more copper reducing power, five times as much as the first dextrin. All the carbohydrates were brought into glucose by sulphuric acid and heat. His investigation had been carried out on this line: half a principle had been tested to find its copper reducing power; the other half had been brought to up glucose, and its reducing power then tested, and a comparison of the two made. Exactly the same occurred in regard to the so-called glycogen, which had no cupric oxide reducing power, and was precipitable by alcohol. When acted upon by ferments it was converted into dextrins, maltose, and glucose. Ordinary ferments reduced dextrins only to maltose ($C_{12}H_{22}O_{11}$); it was impossible to get glucose ($C_{12}H_{24}O_{12}$). To get glucose it was necessary to act upon them by sulphuric acid and heat. But in diabetic urine glucose was met with; for this a glucose-forming ferment was necessary, and this exists in the liver. In the animal system the reverse change took place; glucose was carried up through maltose and dextrin to glycogen and starch. Glucose was converted into maltose in the stomach and intestine; it was not absorbed as glucose. Cane sugar was not converted into glucose, but into maltose in

the alimentary canal. The portal blood contained a quantity of maltose and dextrins, and ultimately glycogen was formed. Dextrin of low cupric oxide reducing power brought into contact with liver and blood out of the body was converted into glycogen. Carbohydrate treated with liver and blood was carried upwards out of that group altogether, and this new principle might be brought down again to carbohydrates by certain ferments. This was the process of assimilation. The carbohydrates were carried out of the group without being converted into glucose. Diabetes was essentially characterized by the non-utilization of these principles; the carbohydrates came into glucose, and were then eliminated. But glucose was eliminated where no carbohydrate is found, because the albuminous molecule was split up into urea and a carbohydrate, which was then reduced to glucose. We had, then, a glucose-forming ferment which was not saliva, blood, muscle, or pancreatic juice. This glucose-ferment was in the liver. All parts of the body, like the liver, undergo a post-mortem change with the increase of the amount of maltose. The glucose ferment only existed in the liver. Venous blood was antagonistic to it, and if an animal be asphyxiated by ether, maltose, not glucose, was found. Arterial blood in the liver gives a glucose ferment; venous blood in the liver gives a maltose ferment. A superabundance of oxygen in the body led to glycosuria (as by inhalation of oxygen or injection of dephibrinated arterial blood into the portal vein). Diabetes depended upon a dilatation of the arteries of the chylopoietic viscera—a vaso-motor paralysis; which allowed the blood to pass to the liver too little deoxygenated. What the liver wants was good venous blood producing a maltose-forming ferment. Simple venous congestion of the liver would never produce diabetes. The hyperæmia of the chylopoietic viscera had been observed in diabetes, both natural and artificial. The severity of diabetes depended upon the area of the vaso-motor paralysis; the area might increase up to the tongue, and then be seen—the tongue intensely red and injected like raw beef. He related the case of a lady, aged fifty-five suffering from diabetes, treated in the ordinary way; sugar disappeared from the urine; seven months later the disease had returned in the form of diabetes insipidus (she was still taking the restricted diet), and he thought the area of the vaso-motor paralysis had then shifted to the kidney. Under treatment by valerian the diabetes insipidus disappeared. Now she was able to take a certain amount of starchy food without passing sugar. In young people the disease was progressive, at first controllable, then uncontrollable. No doubt there was a nerve lesion in association with it.

Dr. Douglas Powell observed that the debate had been useful in indicating more especially the necessity for experimental inquiry into (induced) living pathology, and in physiological chemistry, in order to throw fresh light upon diabetes, and in both these respects Dr. Pavy had redeemed the Society from the reproach of having had no contribution of the kind. He believed that the results of Dr. Pavy's valuable and novel researches would dovetail in with those of Dr. Dickinson showing the existence of nervous lesions. He begged to second Dr. Dickinson's suggestion, that a committee be formed to report upon the specimens from the nervous system shown now and also at any future meeting. Dr. Powell was himself convinced that most of Dr. Dickinson's specimens were examples of positive lesion; whether the result or the cause of the comatose state was a separate question. Dr. Powell believed that the idea still prevailed that a causal affinity existed between

phthisis and diabetes; this view he regarded as due to confusing cases of diabetic phthisis, if there were such, and cases of phthisis occurring in the course of diabetes. In his own experience of chest disease diabetes was infinitely rare, and in five or six years' experience at Brompton, with an average of thirty cases of phthisis of all sorts, stages, and degrees of activity, constantly under his observation, he could recall no case. He had, through the kindness of colleagues and the friendly labors of the resident staff, obtained an examination of the urines of 165 cases of phthisis and sixty-five cases of other chest diseases now in the Brompton Hospital. The specific gravities varied from 1010 to 1035, but in no instance had sugar been found. He would like to have similar statistics from diabetic cases, not, of course, gathered from the last stage, for some form of pulmonary disease carried off a large proportion of all chronic maladies. He believed phthisis and diabetes to have nothing in common; they were not interchangeable by inheritance, and they did not merge into one another, save that some form of phthisis might arise in the course of diabetes, as in any other chronic and exhausting malady.

Mr. Hulke, in closing the discussion, said the debate had been useful as throwing much light of both a negative and a positive kind upon diabetes. Some observers had failed to find any pathology, others had found various lesions, but none of them were absolutely peculiar to diabetes. He thought it would be well to refer the whole matter of the microscopical investigation to a committee. Dr. Pavy's communication was of very great importance, but it was necessary to go beyond the vaso-motor palsy and detect the cause of that.

After the meeting Dr. Radcliffe Crocker demonstrated an easy and expeditious method for the quantitative estimation of sugar, invented by Dr. Duhomme, of Paris. The principle of the method was, chemically, that of Fehling; the mechanical differences consisted in the substitution of two of Limousin's compte gouttes graduated to 2 c.c. and 1 c.c. respectively, for burettes, etc. The test appeared to be easy, accurate, and expeditious.

Mr. Stanley Boyd showed a man with Tubercular Ulceration of the Tongue; and Dr. Hadden showed a specimen of Tubercular Ulceration of the tongue as a card specimen.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Congenital Syphilis of the Larynx.—Purulent Pericarditis treated by Paracentesis and by Free Incision, with Recovery.—Paracentesis Pericardii.

THE ordinary meeting of this Society was held April 24th, Professor J. Marshall, F.R.S., President, in the chair. At the commencement of the proceedings the President announced that the Council proposed the following gentlemen to fill the vacancies among the honorary Fellows: Dr. W. B. Carpenter, F.R.S., Professor W. K. Parker, F.R.S., Dr. Ed. Frankland, F.R.S., and Dr. Allen Thomson, F.R.S.; and as Foreign Honorary Fellows Dr. H. I. Bigelow, of Boston, Professor Charcot, of Paris, Professor Du Bois-Reymond, of Berlin, and M. Pasteur, of Paris. The business consisted of a paper by Dr. Percy Kidd on congenital syphilis of the larynx, and two papers dealing in a most thorough manner with the subject of paracentesis pericardii, by Dr. Samuel West, in which he gave details of a successful case of free drainage for purulent pericarditis (being the second on re-

cord), and a full analysis of seventy-nine cases of pericardial paracentesis. Time did not permit of very full discussion of the numerous points of interest raised.

The following is an abstract of the paper on Two Cases of Congenital Syphilis of the Larynx by Dr. Percy Kidd. The author said the ages of the patients here described were fifteen and eighteen at the time of observation, but symptoms developed at the ages of fourteen and thirteen respectively. In the first case, where laryngitis seemed to have appeared a few months previously, great improvement followed the administration of iodide of potassium. On the contrary, in the second case, where the laryngeal disease was of five years' standing, there were webbing of the vocal cords and polypoid excrescences in the larynx, and here no benefit could be expected from internal remedies. Case 1 is a boy aged fifteen. The family history is indefinite. Mother said to be subject to "rashes." There was a history of cough and shortness of breath for nine months. Three months previously the boy's breathing had become stridulous, and shortly afterwards some dead bone came away from his palate. For three days his breath had been very short and he had lost his voice. The patient is small for his age, speaks in a hoarse whisper; upper incisor teeth distinctly pegged; cornea clear. No cutaneous eruption or scarring. Chest small; superficial veins distended; supra-clavicular spaces drawn in during inspiration. Very slight dullness at both apices, and weak bronchial breathing. Breath sounds generally feeble. Marked scarring of soft and hard palate; scars whitish; surrounding tissue dull red. Larynx: mucous membrane throughout of a dull red color. Vocal cords red and thickened. Ventricular bands and aryepiglottic folds swollen, partially hiding the vocal cords. Movements of the vocal cords diminished greatly; abduction and adduction very imperfect; considerable stenosis of the glottis from swelling of parts and fixation of vocal cords. Rapid improvement under iodide of potassium and inhalations of benzoin. Recovery with slight degree of chronic laryngitis and partial fixation of left vocal cord. Case 2 is a girl, aged eighteen. Family history negative. Onset of symptoms sore-throat and hoarseness at the age of thirteen. The patient attributes the throat affection to some medicine she was given while an in-patient at the French Hospital in Leicester-square soon after her symptoms developed. Reasons are given for doubting this. This patient has been hoarse for five years. The chest shows no signs of disease. Lateral incisor teeth somewhat pegged. Palate, pharynx, and left tonsil marked with whitish scars. Larynx: epiglottis thickened and bent backwards towards the larynx; margin irregular and jagged as if partially eaten away; mucous membrane of epiglottis pale; no present ulceration. Vocal cords adherent to one another at their anterior extremities by a web of a reddish-grey color. On the left cord at its posterior third is a small conical outgrowth. The posterior part of the right ventricular band is occupied by a roundish red swelling, which projects downwards and hides part of the corresponding vocal cord. The left ventricular band at its anterior end is thickened. Vocal cords are pinkish, and move freely. Eyes: slight divergent squint. A high degree of myopia is present. Right eye shows a large patch of choroiditis in the position of the yellow spot. Fundus of left eye healthy.—Dr. Sémon had not the least doubt as to the syphilitic nature of the cases, the lesions described being perfectly characteristic. Although he concurred that the manifestations of congenital syphilis were sometimes much delayed, he mentioned a severe

case of pharyngeal and laryngeal ulceration in a lad of seventeen, who had acquired syphilis two years before. In Dr. Kidd's cases there was no history of the disease being acquired; and it was probable they were congenital cases in which the lesions became manifest at puberty. He had come to regard congenital syphilis of the larynx as less rare than he thought a few years ago, when he communicated two cases to the Pathological Society. Dr. John Mackenzie, who was present on that occasion, had published seventy instances. Still in proportion to the large number of cases of congenital syphilis, laryngeal disease could not be said to be frequent. During the past year Dr. Sémon had seen four cases of congenital syphilis of the larynx, and it was curious that two of the children were brothers, and two were a brother and a sister. With reference to the "web" described in Dr. Kidd's second case, Dr. Sémon remarked that Sommerbrodt, of Breslau, had recorded twenty-four cases, Dr. Parr showed one at the London Congress, and he himself had met with six examples, four of which were syphilitic. He agreed with Dr. Kidd as to the propriety of not attempting any surgical interference unless the symptoms were urgent.—Mr. R. W. Parker said it must be admitted that laryngeal disease was very rare in congenital syphilis, especially ulceration. He had paid much attention to cases of laryngeal obstruction for the past ten or twelve years, and had met with only four cases attributable to syphilis, in which the condition resembled that of the mucous tubercle—a papillary condition of the upper part of the trachea and larynx. Young children are sometimes attacked with acute laryngeal obstruction, and on inquiry a syphilitic history is obtained; the symptoms in such cases yield rapidly to mercurial inunction. In one or two such cases he had found the papillary growths on post-mortem examination. The President pointed out that the lesions described in the paper differed from mucous tubercles, which were earlier manifestations; the fact that the latter were benefited by mercurial treatment, and the former by iodide of potassium, further illustrated this difference. He suggested that the physiological changes undergone by the larynx at puberty might account for the late occurrence of the syphilitic disease, the larynx being then more prone to manifest the disease.—Dr. Kidd, in reply, said that if the syphilis in the second case were acquired, the date of infection would have been at the age of eleven or twelve years, but he had no evidence in support of this, and thought it quite possible that the earlier manifestations of the inherited disease had been overlooked. In both cases there was pegging of the teeth, and the girl had central choroiditis. The laryngeal syphilitic formations were more polypoid in nature and less like mucous tubercles than was formerly supposed. With regard to surgical interference with the "web" in the girls' case, he had thought it inadvisable, there being no respiratory distress.—The President remarked upon the fact that as a general rule attempts to remove cicatricial formations by galvano-cautery, etc., failed. Division by the knife and subsequent stretching of the bands is a preferable way of treating such strictures.

Dr. S. West read a paper on a Case of Purulent Pericarditis treated by Paracentesis and by free Incisions, with Recovery. A boy, aged sixteen, came under treatment with a large pericardial effusion. The symptoms became so urgent that paracentesis was performed. Pus was obtained. Three days later paracentesis was again performed, and subsequently the pericardium was laid freely open, evacuated, washed out, and a drainage-tube inserted. The temperature never rose, and the boy

recovered completely in five weeks, the only feature of interest being an attack of general urticaria, which came on about a week after the operation and lasted three or four days. In support of the diagnosis a case was referred to in which what was supposed to be a mediastinal cyst was frequently punctured, but it proved to be, on post-mortem examination, a case of chronic pericardial effusion. The points of clinical interest discussed were:—1. The absence of any special signs to indicate the nature of the effusion. 2. The operation and the place selected for puncture. 3. The amount of the fluid evacuated. 4. A peculiar epigastric prominence, noticed before paracentesis, which disappeared after operation. 5. The attack of urticaria. 6. The pulsus paradoxus. A short account was then given of the only other recorded case of incision of the pericardium for purulent pericarditis by Professor Rosenstein, of Leyden, which also recovered.—Dr. West also read a paper on the Statistics of Paracentesis Pericardii, with Remarks. A complete list of the recorded cases up to date was given in a tabular form, with the addition of several cases hitherto unpublished. The history of the operation was briefly referred to. The cases were discussed under the headings of:—Sex; age; causes (rheumatic fever, scorbutus, phthisis and pleurisy, miscellaneous, purulent pericarditis); length of illness before operation; the effect of the operation; the nature of the fluid; the quantity of the fluid; the number of punctures; the modes of operation; the place of puncture. The following conclusions were drawn:—1. Paracentesis pericardii is not only justifiable, but an operation which may be safely undertaken with ordinary precautions, for only one case is recorded in which the operation was in itself fatal, and with this exception all the patients were greatly relieved by the removal even of small amounts of fluid, and many recovered completely, who would probably have died had the operation not been performed. 2. The most suitable place for puncture is, in ordinary cases, in the fifth left intercostal space, one inch from the edge of the sternum; but if the pleura be adherent, the puncture may be made safely much further out, and even in the sixth space. 3. The instrument employed should be a trocar and cannula, with or without aspiration. 4. The operation may be performed with advantage, not only in the pericardial effusions of rheumatic or primary origin, but also in those which occur in the later stages of general dropsy, if it should appear that the fluid in the pericardium is adding to the difficulties under which the heart is placed. 5. Purulent pericarditis is best treated on general principles, like empyema. 6. The pericardial sac may be safely opened and drained. 7. This treatment, moreover, appears to be the only one which offers the slightest hope of recovery. 8. The results do not seem to be as unfavorable as those of empyema, for the walls of the cavity are better able to contract rapidly, and thus permit of the obliteration of the cavity.—Mr. Hulke congratulated Dr. West upon his case, and would only remark that it was far safer to dissect down on the pericardium before incising it than to plunge in the knife or trocar incautiously. He recalled a case where the diagnosis of a large pericardial effusion was made, and he was asked to operate. He plunged in a trocar, and was alarmed to find from the jetting of blood and the motion of the trocar that he had struck the heart. Fortunately no harm was done, but, on the contrary, some relief was afforded, and when the patient died subsequently there was found to be a universally adherent pericardium, with a greatly dilated heart.—Dr. Green thought it unusual for friction sound to be absent in purulent pericarditis,

and that Dr. West's case was also remarkable in the upper limit of dulness being at a lower level than was customary in pericardial effusions. He suggested the propriety of exploratory punctures, and believed that in most cases of non-purulent effusion the danger to life was from weakening of the muscular wall rather than from the effusion itself. At the same time Dr. West had shown not only the practicability of drainage in purulent effusions, but the fact that paracentesis may be safely resorted to in cases of serous effusion with relief to the patient.—Dr. Routh thought the presence of pus accounted for the absence of the friction sound, and that this negative sign might be of value in diagnosing the nature of the effused fluid.—Dr. Southey said that the etiology of the case was obscure; there was no evidence of rheumatic fever. In rheumatic pericarditis friction sound is almost invariably present. He thought considerable caution should be used before excluding injury, even if some weeks had elapsed, as a cause of such pericarditis, and he suggested the possibility that the case was one of abscess, primarily extra-pericardial, but extending into the pericardium. Was there any bronchial breathing over the lower lobe of the left lung posteriorly? If not, the idea of extra-pericardial abscess would be strengthened. The orthopnoea was no doubt the chief reason for interference. He agreed with Mr. Hulke as to the danger of pushing in a trocar freely. It would be safer to explore with a fine aspirator needle, and if pus were found, to dissect carefully down and then employ drainage. He knew of three fatal cases; one which he saw himself, where the ventricle was wounded; another is recorded by Bouchut. Probably there were others which Dr. West had not met with, and some unpublished. In 1869 Kussmaul recorded four cases, in one of which he pointed out the *pulsus paradoxus* for the first time.—The President remarked that much bolder methods of opening the pericardium had been suggested—e.g., section of rib-cartilages, trephining the sternum, etc.; but puncture through the intercostal space was amply sufficient. The soft depressed area noticed by Dr. West in the epigastrium might be explicable on the view of mediastinal abscess, and the rapidity of cure was remarkable if the pus were in the pericardium.—Dr. West, in reply, said that he proceeded with great caution, using first a small trocar for exploration; and he quite agreed as to the necessity for caution, seeing how impossible it was sometimes to make a diagnosis from dilated heart with adherent pericardium. The heart has been intentionally tapped in some cases of dilated right ventricle with great relief. In Bouchut's case the puncture was without ill effects, and Dr. West had collected several cases where the heart had been accidentally injured without fatal result. The large amount of effusion and the thickness of the pus accounted for the absence of friction sound. He could not agree with Dr. Green, that the chief danger in pericardial effusion is from myocarditis, but from the mechanical effect of the fluid pressure. The *pulsus paradoxus* was evidence of this, and it had been proved to be produced by the imperfect filling of the heart. The epigastric depression disappeared as soon as the incision was made. He had found the same thing noted in a case published by Dr. Clifford Allbutt. Dr. West, in conclusion, said he would be indebted for references to cases in addition to those he had collected.

—No less than 126 students have entered for the first half of the examination for the diploma in Surgery of the Royal College of Surgeons in Ireland.

Gliomatous Enlargement of the Pons Varolii.—Case of Asymmetry of the Brain, presenting peculiarities which bear upon the Question of the Connection between the Optic Nerves and certain Definite Areas of the Cerebral Cortex.

The ordinary meeting of the Royal Medical and Chirurgical Society was held May 8th, Professor J. Marshall, President, in the chair. Two papers were read dealing with cerebral pathology—one by Dr. Money upon a remarkable symmetrical affection of the pons; the other by Dr. Sharkey, in which corroborative evidence in support of the connection between the angular gyrus and the visual function was afforded.

Dr. Barlow showed an infant with Congenital Absence of both clavicles.

The following is an abstract of the paper on Gliomatous Enlargement of the Pons Varolii, by Dr. Angel Money. The object of the paper was to draw attention to the existence of a remarkable enlargement of the pons Varolii of undoubtedly infrequent occurrence. The disease was remarkable from the enormous increase in size of almost every part of the pons and neighboring parts of the brain; the tendency to implication of one-half of the pons as much as the other is a noteworthy feature. The cases recorded are entitled to further consideration from the light they throw on a condition which in this country has been ill understood. Cases of so-called gelatiniform enlargement of the pons Varolii, published in the St. Bartholomew's Hospital Reports, by Dr. Gee and Dr. Percy Kidd, are unquestionably of the nature of gliomata, and it would seem therefore advisable that the descriptive provisional nomenclature should be abandoned. Virchow, in 1863 (*"Die Krankhaften Geschwülste"*), described the various kinds of gliomata (including the infiltrating forms which give rise to diffuse enlargement) as occurring in any part of the brain, and there seems to be no good reason for the employment of a special name for the disease when it happens to occur in the pons. The first instance here recorded was worthy of remark from the fact that although the disease involved both halves of the pons the symptoms were decidedly unilateral. This kind of thing has been mentioned in other recorded cases. In the second case hæmorrhages into the retina and intestinal mucous membranes were discovered. Though this association may be one of mere coincidence or unreal relationship, yet, looking to the known occurrence of hæmorrhages in various parts of the body, almost undoubtedly as the result of lesions, more especially of the base of the brain, it would seem not unlikely that here also we have to do with a causal connection. The absence of such hard-featured symptoms as hyperpyrexia and glycosuria is worthy of mention, and a partial explanation may possibly be forthcoming in the notion that for the production of such symptoms lesions of sudden onset are required.—The President pointed out the difference between the limited and localized nature of the disease in this instance as compared with glioma of the eyeball, with its great tendency to recur and spread into the brain. He asked whether there was any family history of sarcoma in Dr. Money's cases.—Dr. Gee did not think the symptoms differed from those produced by other diseases of the pons—e.g., tubercular tumours, and he had no doubt that Dr. Money had drawn correct inferences from the microscopical characters of the lesions in referring them to a known category of disease.—Dr. Southey asked whether there was any evidence in support of a view formerly held that these gliomatous infiltrations were due to syphilis.—The Presi-

dent asked Dr. Ferrier if he had inferred anything from the statement that no medullated nerve fibres were found in the diseased part, and how this tallied with the fact that paralysis was not complete.—Dr. Ferrier said that the fact that there was not total paralysis proved that nerve-fibres must have been present, although they might have escaped observation. He had lately under his care a case in which he had diagnosed syphilitic lesion of the upper part of the ascending frontal convolution, and after death an abundant small-celled infiltration was found in this region, in which nerve fibres and cells could only be detected with difficulty. The symmetrical disposition of the lesion and its limitation to the pons were remarkable points in the cases described by Dr. Money. The symptoms were those of disease of the pons; but it would not be possible to diagnose the nature of the lesion. In recording these cases Dr. Money had done great service to pathology.—Dr. Kidd said that when he examined Dr. Gee's case he was not aware that Virchow had spoken of a gliomatous infiltration, but had regarded glioma as a definite form of tumour, nor did microscopical examination show the definite neuroglial structure characteristic of such tumours, but only a small-celled infiltration. There was, then, a difference between this form of disease and glioma proper, although they are probably related. In the case he examined he found numerous axis cylinders, although medullated fibres were not visible.—Dr. Hale White suggested that the non-malignancy of gliomata was probably due to the fact that, unlike sarcomata, they are developed from tissue that is already highly differentiated—i.e., the neuroglia. He had never seen or heard of glioma giving rise to secondary growths. The superficial resemblance which the diseased pons bore to the normal structure was doubtless due to the fact that the lesion was essentially an overgrowth of the neuroglia between the strands of nerves fibres, so that the bands of new tissue would follow the lines of the latter.—Dr. Money, in reply, said there was no family history of sarcoma, but in each case one other child had died from brain disease. It was generally held now that gliomata have nothing to do with syphilis. Although he had said that no medullated fibres could be found in the most diseased parts, he was far from thinking that axis cylinders were absent; indeed, several of the "nuclei" were probably sections of axis cylinders; and in other parts of the pons unaltered ganglion cells were to be seen. "Glioma" was a generic term, and the amount of intercellular substance varied in different forms, of which some were extremely cellular, and might be regarded as sarcomata of the brain. The most important point was, that the general pattern of the brain tissue was preserved in these cases. It was not a true hypertrophy of the neuroglia, but a perverted hypertrophy, in which there was a large production of small cells, with no true neuroglial tissue.

Dr. Seymour J. Sharkey read a paper on a case of Asymmetry of the Brain presenting peculiarities which bear upon the question of the Connection between the Optic Nerves and certain definite Areas of the Cerebral Cortex. The patient, whose age was twenty-five, died in St. Thomas's Hospital, owing to injuries received from the fall of a house. Her right arm and leg were somewhat smaller than their fellows, and the former was rigid. After her death this condition was ascertained to have been congenital, but no observations were made during life, either with regard to this malformation, or with reference to the condition of her special senses, etc. The subject of this communication was primarily the anatomical peculiari-

ties of the brain, and secondarily the physiological conclusions which they suggest. The most striking characteristics of the specimen were:—1. The general slight arrest of development of the left hemisphere. 2. The small size of the corresponding crus cerebri and anterior pyramid. 3. The absence of the angular gyrus and superior temporo-sphenoidal convolution, together with the fusion of some of the other convolutions of the left temporo-sphenoidal lobe. 4. The extreme atrophy of the optic tract, optic thalamus, and corpora geniculata on the same side. It was argued that the knowledge we possess at present of the connection between the central convolutions of the brain and the motor strands justifies us in referring the small and somewhat rigid limbs on the right side, together with the atrophy of the left anterior pyramid and crus cerebri, to the condition of the two ascending central convolutions, and their expansions near the great longitudinal fissure. The atrophy of the left optic tract, optic thalamus, and corpora geniculata must be looked at in connection with the absence of the angular convolution, and with the malformation of the left temporo-sphenoidal lobe. Although, from a consideration of this single anatomical specimen, we are hardly justified in making any more precise assertion, still we can hardly avoid looking upon it as confirmative of the physiological experiments of Ferrier, which point in the same direction, and which seem to indicate that the angular gyrus is in some way bound up with the function of vision. The specimen likewise supports the views that the optic thalamus has some direct connection with sight, and that there is semi and not total decussation of the optic nerves in the chiasma. For the right optic nerve bears a far larger proportion to the left than the left optic tract does to the right. And, finally, the absence of any inequality between the corpora quadrigemina of the two sides supports the theory that these bodies are not in the direct line of fire, so to say, between the retina and the cerebral cortex; though they may be in some way related to the coördination of the ocular muscles, which is necessary for normal vision.—Dr. Ferrier had been much interested in the paper, which detailed carefully and clearly a very important case. He had seen the specimen, and could confirm the fact of the limitation of the atrophy to the angular gyrus and superior temporo-sphenoidal convolution. Unfortunately, as often happens, no clinical history was available. The atrophy of the pyramid complicated the case, but it was, as Dr. Sharkey had stated, doubtless due to the general arrest of development of the left hemisphere. Was there actual sclerosis established? The chief point of the case concerned the angular gyrus, destruction of which he had shown to be followed by temporary blindness. In the experiments described by himself and Dr. Gerald Yeo at Cambridge, three years ago, it was shown that the visual centre comprised not only the angular gyrus, but the occipital lobe also, the former being the more important. Dr. Sharkey's case confirmed this. The case was also of value because the lesion was primarily cerebral, whereas in most recorded cases one has to do with the secondary effect on the brain of the loss of an eye or of a limb. In this respect the fact that the corpora quadrigemina were intact was valuable as throwing light on their function. The case at first sight might not seem to confirm the fact arrived at from experiment, that the temporo-sphenoidal lobe has to do with audition; for there was no atrophy of the auditory nerve like that of the optic tract. Perhaps the connection of the auditory nerve with its nucleus accounted for its immunity. The optic thalamus was probably related to all sensory func-

tions and not specially to vision.—Dr. Money asked if there was any change in color in the wasted convolutions. He had recently examined a case where there was pigmentation of the atrophied gyri, probably due to hæmatoidin.—The President asked whether there was any corresponding cranial asymmetry, whether any difference at all was observed in the relative sizes of the eyes, and any changes in the spinal cord. He also asked as to the relative thickness of the affected parts of the cortex, and observed that it is not probable that the cortical "centres" are strictly defined and limited, but that neighboring parts of the grey matter may share to a slight extent in the functions of these "centres." The fact that the corpora geniculata wasted suggested that these structures are related to the nutrition of the optic tracts, and are not directly concerned in vision proper.—Dr. Sharkey, in reply, said that he could detect no difference in the two sides of the cranium; and none of those who had seen the patient had observed any difference in the eyeballs during life. In the spinal cord there was very definite descending sclerosis, most abundant in the upper cervical region in the posterior part of the lateral column, but there was no change in the tract of direct fibres in the anterior column. He had not yet examined the affected cortex minutely for fear of disturbing the relation of the parts, but had observed no change in its color. The case was admitted into the surgical wards for an injury to the back, and paraplegia was sought for. The condition of the leg was noted, but the upper limb was not observed, nor was any special examination made of the eyes. He had now collected five cases of limited cortical lesions associated with local paralysis, and all of them were confirmatory of Ferrier's experimental conclusions. At the same time recovery of a limb from paralysis due to cortex lesion pointed to the probability that one part of the brain may take on the function of an injured part after a time.

MEDICAL SOCIETY OF LONDON.

The Poison of the Viper and Permanganate of Potash.

At the meeting of this Society, April 16th, Sir Joseph Fayrer, M.D., President, in the chair, a paper was communicated by Dr. G. Badaloni, of Nocera Umbra, on the poison of the Viper and Permanganate of Potash. A full abstract of the paper appeared in our last issue.

The President said that the interest of the paper was enhanced by the fact that there was present that evening Prince Louis-Lucien Bonaparte, who made the first analysis of viper poison, and he, (Sir Joseph) had himself alluded to this discovery of the alkaloid in the virus in his researches published twelve years ago.

Prince Louis-Lucien Bonaparte said that forty years ago he had abandoned the study of chemistry, but he was then doing his best to discover the chemical nature of viper poison, and suggested to physicians at Florence to experiment upon it. He had not studied its physiological action, but confined his researches to the action of the poison upon the chemical composition of the blood. What was the reason why blood, especially human blood, lost its coagulability under the influence of the poison? He thought the change was possibly akin to fermentation, a small quantity setting up changes in a large amount of blood; a small quantity of the alkaloidal principal, echinidine, acting upon the whole mass of blood. This was contrary to Lacerda's theory. Permanganate of potash is strongly oxidizing, and this oxygen ought rather to increase

the activity of the bacteria than destroy them. He was not inclined to believe in Lacerda's results, and great scientific caution must be used in estimating them.—Dr. Broadbent thought that the Prince's remarks were very suggestive. How do these poisons destroy life? By primary action on the nervous system, or on the blood, which then acts upon the nervous and vascular systems? Dr. Wall distinguishes between the effects upon the heart and upon the respiratory system. He agreed with Prince Bonaparte in hesitating before accepting the value of permanganate of potash in viper poisoning. Careless experimenters might easily have been misled by the different intensity of the poison at different seasons of the year. There might also be a difference in the intensity of the poison of the viper and the rattlesnake.—Dr. Williams asked Sir J. Fayrer as to the state of the blood-globules in viper poisoning, and what effect the poison of one viper would have upon another, and what upon different classes of animals.—Dr. Cullimore thought that if the permanganate of potash acted in a chemical manner, and the poison was bacterial, its action ought to be immediate. Oxygen is fatal to micro-organisms. It would be interesting to know what animals Dr. Lacerda experimented upon. He had been informed that during the Civil War in America death from rattlesnake bite was very rare when proper treatment and precaution had been observed. The best treatment was alcohol and cardiac stimulants.—Dr. Routh said the question whether the poison acts directly on the blood or on the nervous system depends upon the intensity of the virus, and it might act in both ways. A potash salt in sufficient quantity acts as a direct poison. The chloride of potassium kills instantly. To inject the permanganate of potash is to introduce a poison. Pasteur had shown the action of oxygen upon bacteria, and why should not peroxide of hydrogen be given, for it yields oxygen far more readily than the permanganate?—Dr. Hicks said the permanganate of potash only gives up oxygen to substances in its immediate vicinity. Its action would therefore be purely local, and it could not be of use in the general blood current.—The President, remarking upon the extent of the subject, said he would limit himself to one or two of the most important points. He wished the author of the paper were in the tropics, where he could experimentalize better on the subject. Permanganate of potash is a chemical antidote to snake poison, not a physiological antidote. It has no effect on a poisoned animal or man, but it does decompose the poison out of the body. The poison enters the system very quickly. About 90 per cent. are bitten in the extremities, and the part can be isolated to a certain extent, but it rarely happens that it is possible to apply any antidote. Permanganate of potash could be used locally to destroy the poison in the wound when a man is bitten and help is near for a ligature to be applied above the wound at once. In cutting out the part it is necessary to remove all the tissues stained the peculiar red tint caused by snake bites. Possibly the injection of a stronger solution of the permanganate may be required for its local effects; but he was sure it was of no value when the poison had once got into the system. He believed that great good would result from the experiments made by himself, L. Brunton, Lacerda, Ewart, Wall, and others. There is no physiological antidote to the effect of snake poison upon the nervous system, no more than to a bullet passing through the brain. Prince Bonaparte and others worked under great disadvantages, having very dilute poisons to work with. The poison of the echis is infinitely more deadly than that of other

much larger poisonous snakes. It is very rare for a healthy person to die from a viper bite. As Dr. Wall has clearly demonstrated, there are two or three totally distinct snake poisons. The teeth of a viper have no motion, but the maxillary bone moves. In the colubrine snake the maxilla is larger and hardly movable at all, but in all the poisonous snakes the maxilla is devoted entirely to the poison fangs. The poison of the colubrine snake kills by paralysis of respiration, both centrally and peripherally. The viperine acts at first upon the blood; it kills rapidly, producing convulsions, hæmorrhages and non-coagulability of blood. He had never seen any microscopical change in this blood; the corpuscles are a little crenated. After cobra poisoning the blood coagulates firmly, except occasionally in man. Cobra poison in a vein kills (man) in half an hour. The action of the poison is slower upon fish, snakes, and lizards; they become quiet and sluggish and then die. The bite of a cobra does no harm to another cobra, but kills a viper in from two to three days, either from the effect of the wound or its special poison. Care in nursing will often determine whether a man shall live or die when the dose of poison is small; but if a man be bitten by a vigorous cobra he certainly will die therefrom unless the entry of the poison into the blood be at once prevented. Stimulants are useful to prolong life. He did not think it likely that suction would extract much poison from the puncture, the poison being absorbed through the mucous membrane. There need be no abrasion of the skin, and there is danger to the person sucking the wound given by a deadly snake. The poison kills if passed into a rabbit's stomach or into a bird's gizzard.—H.I.H. Prince Louis-Lucien Bonaparte said that Sir J. Fayrer had proved the difference between viperine and colubrine; they were chemically different, the one coagulating, the other not coagulating, albumen. Analogy pointed to the difference in the chemical composition of the poisons of different species of snakes.

Spinal Deformity, with Fragility of Bones.—Foreign Body in the Pterygoid Region.—Pyæmia in a Child associated with Cystitis and Pyelo nephritis.

A meeting of the above Society was held on April 23rd, Sir Joseph Fayrer, President, in the chair.

Mr. Pearce Gould showed a case of Ununited Fracture of the Olecranon on which he had performed antiseptic suture of the fragments.

Dr. Lee read a paper on a case of Spinal Deformity and Fragility of Bone in its relation to Insanity (patient shown). He remarked that the disease of bones which caused deformities were obscure in their origin and difficult to explain. The pathological changes alone did not assist us in understanding them, and it was rather by observing the subtle influences of the hereditary peculiarities and close study of the clinical history of cases that we might arrive at such a knowledge of the causes as to enable us to treat the diseases with advantage. The man was thirty-nine years old, and had lost in seven years nearly five inches and a half in height from curvature of the spine, tibia, and other bones. He had broken both humeri at different times, as well as the clavicles and the patellæ. There was a strong family history of insanity and dipsomania. This man had not taken stimulants for twenty-five years. The exact nature of the case was doubtful, as there was some thickening of the bones and other symptoms of osteitis deformans; at the same time there were some of the ordinary symptoms of malacosteon.

Could the two conditions co-exist?—Dr. Symes Thompson asked if there was anything like the gastric crises seen in locomotor ataxy. The case was unlike the ordinary cases of fragility of bone in progressive muscular atrophy, Charcot's disease, osteitis or mollities ossium.—Mr. Hugh Smith asked if the urine contained an excess of phosphates.—Sir J. Fayrer asked if Dr. Lee had inquired into the statistics of lunatic asylums as to fragility of bones. The disease was not inflammatory. Had any other members of the family suffered in the same way? He mentioned a case where a tibia became bent from chronic osteitis, following an abscess which had been cured by trephining.—Dr. Lee, in reply, said there was no gastric crises nor marked excess of phosphates. Its resemblance to rickets had attracted his notice. In cases of rapid bending of bones after fever, the bones recover quickly, and these cases differ from the common form of rickets. Rickets was associated with nervous depression. Fragility occurs in paralysis of the insane, and osteomalacia had been seen in melancholia. In the present case no other members of the family were affected.

Mr. Hugh Smith related a case of Foreign Body in the Pterygoid Region. In March last a boy, aged six years, was brought to Mr. Henry Smith, having fallen with a piece of clay pipe stem between his teeth. On rising from the ground blood flowed freely from the mouth, and a small opening was visible internal to the second lower molar on the right side. On passing a probe a rough surface was felt at the depth of half an inch. Chloroform was given a week later, but owing to the rigidity of the jaws an attempt to remove the foreign body failed. Five weeks later chloroform was again given, the mouth being kept open with Rose's gag; the sinus leading to the rough surface was enlarged by incision, and a piece of pipe-stem one inch long was removed with the nasal polypus forceps. Mr. Smith also detailed a similar case which came under the care of his father, Mr. Henry Smith, twenty years ago. A man while smoking received a violent blow in the face. Five or six months afterwards he suffered from a painful swelling behind the angle of the jaw proceeding from an abscess, and eventually from its sac was taken a piece of pipe-stem an inch long. In both of these cases the foreign body entered the soft tissues internal to the ascending ramus of the jaw.—Sir J. Fayrer mentioned the case of an officer at Darjeeling, who fell on the stump of a bamboo and was impaled. He remained there for many hours; the bowel was injured and also the bladder. He was sent to Calcutta, and after great suffering a stone was eventually found in the bladder around a fragment of bamboo.—Dr. Isambard Owen referred to a specimen in the museum of St. George's Hospital of a hat-peg broken off through the stem. It had been lodged in the orbit, and was extracted, the patient recovering.—Mr. Alban Doran said there was often no suppuration around steel instruments—e.g., a prong of a fork.—Mr. Pearce Gould referred to the fact that many foreign bodies remain in the tissues without setting up suppuration, which appeared in many cases to be due to septic particles carried by them into the wound.—Sir J. Fayrer added that foreign bodies caused mischief by the great tearing and bruising of the tissues. He had known bullets to remain encysted in the body for many years without injury.—Dr. Day mentioned a case where a fish-bone in the rectum caused long-continued and profuse hæmorrhage, which ceased on the detection and removal of the foreign body.—Mr. Black knew of a case of intractable rectal abscess, where, at the end of a year, a piece of trouser was extracted, which had been carried in by impalement some years before.

Dr. Day read notes of a fatal case of supposed Pyæmia in a Female Child, associated with extensive changes in both Kidneys and Bladder. The child was twelve years and a half old, and came under care on Feb. 10th, 1883, suffering from constant sickness and failing strength. Five years previously she was said to have had measles and scarlet fever. Two days after admission a large and prominent tumour was detected in the abdomen, extending from the umbilicus to the pubes. This proved to be the bladder; a catheter was passed with difficulty, owing to contraction of the urethral orifice, and twenty-six ounces of acid urine containing a little pus were drawn off. A petechial rash appeared, and became general. On the 23rd she became delirious, and on the 25th she died. After death the right kidney weighed three ounces. Its capsule was thickened and universally adherent; the pelvis was dilated, containing four ounces of turbid urine. The left kidney weighed about five ounces, its surface covered with points of suppuration and small abscesses; the ureter dilated and its walls thickened. The bladder had thickened walls and greatly congested lining membrane. Dr. Day remarked that retention of urine is rare in children, especially in girls. The cause in this case was obscure. The contracted urethra might account for the bladder condition; and he thought the fatal illness was of pyæmic nature.—Dr. Amand Routh thought the cystitis preceded the contracted condition of the urethra.—Mr. Pearce Gould thought the case to be one of surgical kidney caused by stricture of the urethra.—Dr. Routh agreed with Mr. Gould. He asked whether the child had syphilis. A stricture might often occur from a cicatrizing chancre; or was there any history of masturbation?—Dr. Ewart suggested that there was local tuberculosis of the urinary tract. If it was pyæmia, it was local and not general, and death resulted from uræmia.—Dr. Day said there was no evidence of vulvitis or of masturbation, nor of syphilis. The symptoms were not those of uræmia. There was no tuberculosis.

CLINICAL SOCIETY OF LONDON.

Lepra Tuberculosa.—Excision of Lip.—Symmetrical Gangrene.—Subcutaneous Nodules.

THE ordinary meeting of the above Society was held on Friday, April 27th, Dr. Andrew Clark, President, in the chair. Three papers were read, and two, by Dr. Stephen Mackenzie and Dr. Dyce Duckworth, were, by the consent of the authors, taken as read, on account of the great number of communications still in the hands of the secretaries. A case of spondylitis deformans was shown by Mr. Glutton, a case of multiple nodes in a patient the subject of congenital syphilis by Dr. H. Radcliffe Crocker, and a case of tubercular ulceration of the palate by Dr. Barlow.

Dr. W. J. Tyson showed a case of *Lepra Tuberculosa*. R. C. S., aged sixteen, was born in Ireland, and when two months old went to India, and remained there until he was six, then returned to Ireland and has not been abroad since. His family history gave no clue to his case. He was quite well until two years ago, when the present condition of face first began to show itself. The lad is physically strong and fairly well made; height 4 ft. 8½ in.; his hair is reddish and his eyes blue. He does not seem mentally dull. The appearance of the face was characteristic of the disease, and had, as many have, a somewhat lion-like appearance; the skin was soft to the feel, thickened, and of a brownish-red color; on his chin and just underneath it were about a dozen small elevations

(tubercles), varying in size from a mustard-seed to a pea. On the trunk in front and behind there was a yellowish-brown mottling. The chest and abdomen were healthy. There was no albumen in the urine. Just below the right buttock there was a patch of flattened tubercles, and over the left olecranon a softish mass of the size of half a walnut. The hands were generally cold, and the skin thickened; around each wrist-joint there were a few tubercles. The skin over the feet was red, thickened, and scale-like in appearance. All the joints were sound. Hoarseness of voice had come on quite recently. There was no anæsthesia of the skin. His diet did not seem to have been abnormal. There were no signs of nerve lesion of any kind, and no joint affection.—Dr. Southey said the case was very interesting, as presenting all the signs of the earlier stage of leprosy. Two or three years hence the boy would show loss of sensation in the ends of the fingers; the fingers would become less mobile, and so a real distress to the patient, and such patients would often cut off their fingers themselves. Anæsthetic leprosy began quite differently by erythema of the skin of the face, hands, and arms; these were thickened, red and raised, and they became insensible first in the centre; the insensibility was limited to the skin; there were no tubercles in the skin. In the later stages of tubercular leprosy albuminuria came on with granular degeneration of the kidneys.—Mr. Startin said that there was slight ulceration commencing in the lobes of the boy's ears. He had seen a case of leprosy coming on ten years after the man left India.—Dr. Clark asked if Dr. Tyson had examined for bacilli.—Dr. Southey said there was frequent micturition preceding the albuminuria. The granular kidney was due to a general increase of the connective tissue of the kidney, and as also in the liver and other organs.—Dr. Dyce Duckworth referred to the report on a case of leprosy that died in Middlesex Hospital, published in the Pathological Society's Transactions.—Dr. Tyson said he could get no further history than that given. He did not think the very slight ulceration behind each ear was specific; he also doubted the thickening of the ulnar nerve. There was no frequency of micturition. He had not examined for bacilli.—Dr. Andrew Clark nominated Drs. Southey, Dyce Duckworth, Thin, and Tyson as a committee to investigate the case for bacilli.

Mr. Richard Barwell read a paper on a case of Removing a large portion of the Upper Lip without deforming the face.—George S., aged sixty-one, much addicted to smoking short clay pipes, came under Mr. Barwell's care with epithelioma of the upper lip. The growth was close to the corner of the mouth, but did not involve the commissure; and was so extensive that at least two-thirds of the lateral half of the lip had to be removed in eradicating the disease. The following operation was devised and performed, Nov. 4th, 1882: The base line of the triangle requiring removal was measured, and an equal line marked by a superficial incision extending from the corner of the mouth directly outward. The other sides of the triangle, also measured, were similarly traced from this line downward towards the ramus of the jaw. Thus was traced outside and below the mouth a triangular flap exactly like that to be removed from the upper lip, but reversed. The first—the horizontal—incision was now deepened down to, but not into, the mucous membrane; then the two lateral limbs of the triangle were incised through all tissues into the mouth, and some bleeding vessels were twisted. The thick tissues of the flap were dissected from the mucous membrane left hanging to the horizontal incision, to which the extreme point being sacrificed, it was stitched,

thus giving to that part a red border. The next step was the excision of the epithelioma along the lines already traced and measured. The edges of the lower of what may be called the complementary triangle were now brought together with twisted suture. In doing this the horizontal base line of the complementary triangle was necessarily shifted inwards, and coming to lie above the lower lip took the place of that part of the upper lip which had been removed with the cancer. The new red border, made by turning up the mucous membrane of the cheek, imitated the natural red of the lip. The edges of the wound in the upper lip were now brought together with harelip pins, and the new mucous edging sewn with horsehair, both to where it joined the old and at the commissure of the mouth. When all was complete, no deformity was left. The man recovered rapidly; and when seen two months after operation his mouth was as nearly perfect in form as previous to operation, nor did its movements appear in any way irregular or constrained. The disease rapidly recurred, and prevented Mr. Barwell from showing the case.—Dr. Andrew Clark remarked that possibly the most important factor in causing epithelioma of the lip was irritation, which stimulated growth and repressed development.

Dr. Southey related a case of Tachetic Symmetrical Gangrene and showed the patient. Frank N—, aged nine, admitted into Matthew ward, St. Bartholomew's Hospital, November 25th, 1881, was much emaciated, his hair thin and falling off, abdomen empty and retracted; skin dry, and he was in a curious, excitable, semi-delirious mental state. He presented a gangrene of the tip of his right index finger, all his extremities felt cold, and he had insomnia. His pulse was 148, very feeble; respiration 32; temperature 99°. His heart beat with feeble impulse in normal situation. There was no increase of normal cardiac dulness; no cardiac murmur; no physical signs of lung disease. Neither liver nor spleen transcended their normal limits. His appetite was bad; he had had no sickness; bowels acted once daily; tongue clean and moist; micturition gave no pain; urine scanty, not abnormal. After a few days the thumb and second finger of the same (right) hand were involved, became first red and throbbled, then livid and finally gangrenous. On December 5th an exactly similar spot occurred on the pinna of the right ear, and on the extremity of his nose, and the tip of the middle finger of his right hand. A little later, subcutaneous mottlings (*tachetéés*) appeared all over his trunk and limbs, and developed into a raised rash like urticaria tuberosa or erythema tuberculatum. The spots first itched, then became painful and tender, but gradually subsided, leaving only some pigmentation to mark their sites. Finally, all the fingers and the thumb of the right hand gangrened and slowly separated, also the thumb, index, and little finger of the left hand. He passed into a condition of most extreme prostration, with bronchopneumonia of both lungs, and only very slowly and gradually recovered from it. In January, 1882, a new and interesting clinical feature was manifested—namely, intermittent true hæmaturia, bloody urine being passed alternately with normal colored, non-albuminous urine. Some days distinct blood cells were passed with the urine, on others, blood-coloring matter without blood cells; on others, albumen with blood enough to give the guaiacum reaction only. Oxalate crystals were present in great abundance when the hæmaturia was abundant, and *vice versa*. No tube casts were ever noticed. All symptoms of urinary disorder disappeared in July, 1882, when the child was discharged well, but with the loss of his fingers. He had been seen several times since.

The author next cited some parallel examples of this malady, which he referred to vaso-motor disturbance.—Dr. A. Clark asked if there was any history of rheumatic gout; such patches of gangrene were not uncommon in so-called rheumatic gout.—Dr. Barlow had never seen so severe a case as this, but he had seen two or three cases of Reynaud's disease. The first was that of a man, aged thirty-five; he was said to have rheumatism; he had severe pains in his legs, followed by patches of very bluish redness; this he had had for several years, at times, during the winter months. Dr. Barlow first saw him a few days after one of these attacks, and he then had a patch of gangrene on one toe, and a livid patch near one hip. He had also seen the disease in two girls who first suffered at the age of three years and a half. They suffered monthly in the winter. When first seen, one of them had one limb quite black, and was in extreme pain; after three hours the color passed off and the child was quite well. He saw several such attacks in this child. The other little girl had her attack in cold weather; she had with several of her attacks violent pain in the stomach, and two or three hours after the attack she passed urine very dark from hæmatin—not blood-corpuscles—and containing oxalates. She did not pass the dark urine more than once after the attack. The disease seemed to be like paroxysmal hæmaturia in coming on in cold weather, and also in its mode of onset. Cold was much better than warmth for these attacks. He referred to a case of paroxysmal hæmaturia which appeared to be benefited by washing in cold water, while the patient had been accustomed to bathing in very hot water. Reynaud had used the constant current down the spine with excellent effects, and one of his patients, the man, was distinctly benefited by this treatment. He had not found any proof of rheumatism or gout in any of his cases. Mr. Hutchinson had described an end-joint arthritis which he associated with Reynaud's disease. Dr. Barlow had a patient with symmetrical fibrous ankylosis of fingers, and he had great coldness in his extremities, but not patches of local asphyxia.—Mr. Cripps thought this disease was essentially local, and that the disease was essentially a gangrene. No embolism had ever been found. There was a great analogy to ordinary frostbite in which there was no general disease. Young women often have cold hands and feet, and these easily get chilblains from a feeble action of the heart. He referred to a case of a woman very liable to chilblains, who married, and six weeks after confinement had gangrene of both hands, legs, and ears. The sudden call of the child-birth caused gangrene in a patient with a feeble circulation. He thought cold was a very dangerous application to parts already gangrenous. Opium was the drug of most value.—Dr. Barlow said he had only recommended cold for localized asphyxia. Reynaud had found spasm of the arterioles of the retina in three cases.—Dr. Mahomed referred to a case under Dr. Wilks of symmetrical gangrene and intermittent hæmaturia and hæmatinuria. He thought the disease was quite different from the cases referred to by Mr. Cripps; these people have not a feeble circulation, the early stage is like that of factitious urticaria. He referred to the case of a woman who showed the disease in a very chronic form. She had had the disease for seven or eight years. When first seen her fingers were blue, with black tips, like severe chilblain with gangrene added to it. In the summer the hands recovered considerably, and became almost well. There was no albuminuria or hæmatinuria.—Mr. Symonds said that the case first referred to by Dr. Mahomed was now well. He also mentioned a patient who suffers from chilblains and has lost the tips of two

fingers. She had none of the general symptoms of this disease. A girl from whom he had removed the ulna came to him the other day with well-marked purpura and hæmaturia.—Dr. Southey replied to Mr. Cripps that he considered the disease as a general disorder dependent probably upon disturbance of a centre in the upper part of the spinal cord regulating the vaso-motor system. He thought we were quite ignorant of the true etiology of the disease. There appeared to be spasm of the arterioles, which in rare cases passes on to gangrene.

Abstract of Dr. Stephen Mackenzie's paper on a case of Subcutaneous Nodules occurring in a patient the subject of Syphilis, and with very indefinite connection with Rheumatism. The patient was a married woman, aged forty, who had never had any important illness till three years ago, when she apparently had syphilis. She came under care for a tertiary syphilide, and during examination it was discovered that she had several subcutaneous nodules. In all, eight have been detected, which vary in size from a hemp seed to a split pea. The skin over them is natural, and they are all movable. They cause no pain, except when pressure is made on them. Two are situated along the posterior border of the ulna, and the remainder, with the exception of one in the gluteal subcutaneous tissue, beneath the skin of the thumbs and fingers. The first she noticed about two years ago, and it has increased in size. None that she has observed have disappeared. As regards rheumatism, the only symptoms which could be in any way construed as due to this disease were some pains in the legs eight years previously, for which she used a liniment. She has never had chorea. There is no evidence of heart disease, nor of arthritis, present or past. The physical characters of the subcutaneous nodules are exactly those of the nodules described by Drs. Barlow and Warner in connection with rheumatism and allied affections. The interest in the case lies in the very indefinite, if at all existing, connection between the nodules and rheumatism. The patient had not suffered from any distinct rheumatic symptoms, nor is there any family tendency to that affection. The association of the nodules with the syphiloderma may be fortuitous. The duration of one of the nodules is greater than in any of the series of cases recorded by Drs. Barlow and Warner. The longest time they noticed nodules to persist without diminution was five months.

Abstract of Dr. Dyce Duckworth's paper on a case of Rheumatismal, Cutaneous, Subcutaneous, and Periosteal Nodules. M. F—, aged thirty-eight, a married woman with one child, came under Mr. Langton's care at St. Bartholomew's, in December, 1882, for the treatment of multiple fibrous nodules on the arms and legs. She was active and robust, with fresh, rather florid complexion and fair hair. Teeth nearly all decayed and lost. The history was that a "lump" first came on the right elbow in September, 1879, another on the right knee soon followed, and others have appeared on the limbs from time to time. They were found in the several positions hereafter mentioned. Right ulna: A large tumour (size of a penny), freely movable, not adherent to the periosteum. Below this two others, much smaller, adherent to the periosteum. None over the radius; one firmly attached to the anterior ligament of the wrist; one in the palm of the hand; and one on the third phalanx of little finger. Left ulna: One four inches below olecranon, small, slightly movable, not adherent to the skin. None on the radius. On the palm of the hand six small nodules, adherent to the skin. Right leg: One over the lower angle of the patella,

movable, not attached to the bone, about the size of a penny. Another, two inches below patella, much firmer, freely movable, and adherent to the skin. Numerous small ones on the crest of the tibia, to within five inches of the ankle, firmly adherent to the periosteum. Several over the upper part of the fibula, firmly adherent to the periosteum. No nodules found on the scalp, scapulae, spinous processes of vertebrae, or feet. The tumours were very painful, and ached more in cold weather. There was no personal history of rheumatism or of chorea in this patient. Her mother, however, was rheumatic, and a sister had had three or four attacks of rheumatic fever. Examination of the heart revealed nothing worthy of note. There was perhaps doubtful roughness of the first sound of the apex. Iodide of potassium was given, and during the past three months there had been a gradual reduction in the size of the nodules, and some of them had become softer. Having regard to the clinical features of this case, and to the family rheumatic predisposition, Dr. Duckworth ventured to call these nodules rheumatic in their nature, and he believed that further study of these cases showed that there are several types or varieties of them. This case, as well as that one exhibited by him at the beginning of this session to the Society, illustrated a form met with in adults in which the nodules are very persistent, and are also attached to the skin and periosteum. Amongst the first cases brought forward by Drs. Barlow and Warner, the nodules were found to be commonest in children and young persons, to be subcutaneous, not to have any periosteal attachment, and not to last more than a few weeks or months. In this instance, the nodules have lasted for two years and six months, and in the other for one year and six months.

HARVEIAN SOCIETY OF LONDON.

At the meeting of this Society held on April 5th, 1883, the President, Dr. E. Symes Thompson, in the chair, Dr. Broadbent showed a patient who was suffering from a Peculiar Disturbance of the Capillary Circulation. The patient, eight years ago had a sunstroke, which for a time rendered him insensible; previously to this he had frequently suffered from pain in the occipital region and vertigo, which since that time had been much aggravated. Seven weeks ago, while looking over a bridge, he was seized with a sudden and violent pain at the back of the head, and intense giddiness, upon which supervened unconsciousness, lasting for fifteen minutes; since then he has had several similar attacks, as many as three or four a week. On speaking to the patient a blush appeared on the face which extended over the chest and back, and lasted several minutes, leaving a mottling of the skin which somewhat resembled roseola. The "tache cérébrale," again, was unusually well marked, a line of vivid redness appearing in the track of the finger nail drawn over the skin. In the course of his remarks Dr. Broadbent stated that this was a condition occasionally seen when the nervous system was broken down by overwork and strain. The "tache cérébrale" was most commonly seen in tubercular meningitis, but it was often present in other acute cerebral diseases and sometimes in enteric fever; its occurrence in association with prostration of the nervous system without fever was interesting and suggestive.

Dr. Sydney Phillips showed a case of Congenital Dislocation of both Radia. The patient was a girl, aged seventeen, otherwise well developed.

The head of each radius formed a well-marked prominence behind the external condyle of the humerus. The elbow-joint could be fully extended by the patient, and could be flexed to almost the normal degree, but only with the hand in a semi-pronated position. The head of the radius could be rotated to a small extent on the external condyle of the humerus, and the various prominences of the elbow-joint, as well as the head of the radius itself, were fully developed. The deformity was noticed almost immediately after the birth of the patient. Cases of dislocation of the bones of the forearm were stated ("Holmes' Principles and Practice of Surgery") to have occurred from traction on the limb by the accoucheur during delivery, but this did not appear to have been the cause in the present case, as the deformity was symmetrical on the two sides, and there had been no difficulty in the birth of the child. Dr. Phillips thought that, possibly, the radius was developed in the abnormal position.

Dr. A. J. Silcock exhibited a Kidney, Bladder, and Testicle taken from a patient who had recently died in St. Mary's Hospital. The left kidney was much enlarged, weighing twelve ounces, and very firmly adherent to the perinephritic fat. Scattered through its substance were numerous milky caseous tubercles, which had in many cases coalesced into patches of much larger extent. The mucous membrane of the ureters and pelvis were beset with small circular ulcers and submucous caseous deposits. A few caseous nodules were found in the right kidney, and both ureters were considerably dilated. The bladder showed a large number of ulcers, varying in size from a pin's head to a florin, the larger ones extending deeply into the submucous tissue. When removed from the body the mucous membrane was vividly injected. The prostate was slightly, but irregularly, enlarged from the deposition of caseous matter in its substance, the vesiculæ seminales and vasa deferentia on both sides being similarly affected. Microscopically the process was essentially an intertubal growth of a small-celled granulation-like tissue, and tending to caseation or to the formation of ill-developed fibrous tissue. As regards other organs, tubercular ulcers were present in the intestines, and grey milky tubercles in the lungs, with extensive recent tubercular pneumonia. The disease, so far as the genito-urinary tract was concerned, seemed to have commenced in the left kidney and spread therefrom to the bladder, prostate, and right kidney, the patient eventually succumbing to the pneumonia. His reason for supposing the disease to have begun in the kidney and travelled downwards was that that organ was caseous, whereas he had never before seen a tubercular testis in such an early stage.

Dr. John Williams next read a communication on Antiseptics in Midwifery in Lying-in Hospitals and Private Practice. He detailed the means taken at the Hospital for Women and Children, for avoiding septic infection after childbirth; these means, shortly, were perfect cleanliness in the patients themselves, strict attention to the state of the wards, which were cleansed daily and were periodically cleared of patients and disinfected with sulphur; during the act of parturition, antiseptic inunction of the vagina and of the head of the child at its descent during each pain, and after delivery, daily vaginal douches with warm water. By such means the mortality of the institution had been much decreased, being now 1 in 200. He compared this with the rate met with in private practice, which, he said, would be much higher if the large number of deaths from puerperal fever—but returned in the certificates as due to pleurisy,

pneumonia, and peritonitis—were taken into account.—Dr. Meadows remarked on the lowness of the death-rate obtained by Dr. Williams, but had seen a similar plan of treatment carried out in Russia as long ago as sixteen years. He deprecated the practice of intra-uterine injections, and remarked that the source of septic infection was often from within; a poison being bred in the maternal passages, a result of a diseased condition of the secretions.—Dr. Hickman thought that washing out of the vagina shortly after delivery was just as dangerous as intra-uterine injection, though after a few days vaginal douches became perfectly safe.—The President, Dr. Norman Kerr, Dr. Lamb, Dr. Alderson, and Dr. Wells took part in the discussion, and Dr. Williams replied.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

The Immediate Causation of Optic Neuritis in Intracranial Disease.—Recovery from Mild Sympathetic Ophthalmia.—New Registering Perimeter.—Peculiar Changes at the Yellow Spot.—New Refraction Ophthalmoscope.—Asthenopia.—Pseudo-Glioma.

THE ordinary meeting of this Society was held May 10th, W. Bowman, Esq., F.R.S., President, in the chair. At the commencement of the proceedings the President reminded the members that at the next meeting, on June 7th, a debate would be opened by Dr. Gowers upon Eye Symptoms in Diseases of the Spinal Cord (*vide infra*); and that if necessary the discussion would be continued on the following evening.

A paper entitled Remarks on the Immediate Causation of Optic Neuritis in Cases of Intracranial Disease was communicated by Dr. Walter Edmunds and Mr. J. B. Lawford. It was based on the examination of the optic nerves in eighteen cases—namely, eight of head injuries, two of tubercular meningitis, two of tumours of the dura mater at the base of the brain, two of cerebellar tumour, and two of cerebral tumour. The cases occurred consecutively at St. Thomas's Hospital. The examination of the optic nerves showed inflammation when they were affected at all, often more intense at the peripheral part and in the meninges, of the nerves. The authors inferred from this that the inflammation was communicated to the nerve from its meninges, down which it extended from the meninges at the base of the brain. This view was further supported by an analysis of the cases. The alternative theory of a descending cerebritis was criticised, and considered to be less well founded. Microscopic sections and drawings were exhibited.—The President asked if the inflammatory changes were more marked on the outer surface of the nerve than in its interior, for, if so, the fact would support the authors' contention as to the origin of the neuritis.—Dr. Edmunds replied that the changes were more marked at the circumference than in the substance of the nerve.—Dr. Brailey said the question was one to be decided by a careful balancing of microscopical evidence, and therefore there was much to be said for the view maintained by the authors. It seemed scarcely consistent with that view that there should be so little inflammation of the disc itself; and he was inclined to attribute the swelling of the disc to oedema. In renal disease the white patches are largely due to swelling of nerve fibres from oedema. In the case of papillitis secondary to meningitis, might not the disc suffer from inflammatory oedema because of the nerve at this point being free from the pressure exerted by the sheath.

Mr. Jennings Milles read notes of Five Cases of Recovery from Mild Sympathetic Ophthalmitis, the clinical characters of which were very similar. In all the cases there was a wound of the cornea, in conjunction with a wound of the ciliary region, or entanglement of the iris. The attack of sympathetic inflammation was of a very mild type, consisting of iritis serosa without any posterior synechiae. There was very slight ciliary congestion, and no pain. In every case the sympathizing eye made a rapid and uninterrupted recovery. In three cases the exciting eye was enucleated directly symptoms of sympathetic inflammation manifested themselves. In one case, excision was not performed till twelve months after all symptoms had disappeared; and in one case excision was performed twenty-two days before sympathetic inflammation appeared. This last case was also remarkable from the fact that the exciting cause of the disease was an extraction of cataract, which had been performed fifteen days previous to the excision. Mr. Milles showed some micro-photographs, illustrating the conditions of irido-cyclitis and neuro-retinitis found in the excised eyes. He stated that he was indebted to Mr. Watson Cheyne for being able to exhibit them. On the question of treatment, the cases were opposed to the dictum of Mauthner, that "one dare not excise in serous iritis;" but clearly proved that excision did no harm. On the other hand, they did not support the view that excision had any power in modifying or arresting the progress of sympathetic ophthalmitis, when once started. Stress was laid on the great importance of the constant use of atropine, and the removal of all sources of irritation, chiefly by the rigid exclusion of light, and by keeping the patient in a dark room, with a bandage over the eyes.—Mr. Nettleship said that he must apologize to Mr. Snell for having mislaid a case which he had contributed on this subject, and which would have now to be read subsequently. The case was interesting, especially in connection with the treatment employed, and he would give an outline of it. A young man received a punctured wound in the left ciliary region by a large needle. Sympathetic iritis of the right eye ensued in a few weeks. Mr. Snell prescribed atropine and rest, but after two or three days the pupil remained undilated. A small prolapse of the iris had occurred at the wound in the exciting eye, and Mr. Snell performed a sort of sclerotomy through the prolapse, removing what he could. In two days after the operation the right pupil dilated, and recovery took place.—Mr. Power had had large experience of injuries to the eye at St. Bartholomew's Hospital, Chatham, amongst the dockyard laborers, from particles of iron becoming detached in driving in rivets. When the injury is very severe, the eyeball ruptured, the iris much damaged, the only course is to remove the globe at once. But there are many other cases in which there is merely a punctured wound, the iris protruding to a certain extent, and in which often an operation is objected to by the patient. In such a case Mr. Power is in the habit of making a large iridectomy with a keratome, clearing the iris freely away from the edges of the wound so as to avoid its being strained. He had had excellent results from this practice. Both eyes must be bandaged, and the patient left in the dark for two or three weeks after the operation. When the lens is damaged it is well to remove the eyeball. It is bad practice to simply snip off the portion of prolapsed iris.—Mr. Couper said that in two of the cases recorded in the paper the sympathetic attack was very mild; in one extremely so; and in these we might trust to treatment. But what ground is there for believing that an attack of sympathetic inflammation

will continue to be a slight one? A severe attack may supervene and destroy the eye, and treatment come too late. If we may judge from his own cases, and that of Mr. Tweedy, which the author related in the paper, it would seem as if early excision arrests the progress of sympathetic inflammation. In one of his cases this attack was so severe that traces of plastic iritis remained a year afterwards, but with normal vision. In spite of the good vision in the injured eye, he thought it was right to excise when the sympathetic inflammation showed itself.

Mr. Adams Frost mentioned a case under the care of Mr. Warren Tay. A girl, ten years old, was wounded in the right eye by scissors, the wound extending to the sclero-corneal junction. Seven weeks afterwards, the wound had healed, the iris adhered to it, but there was no affection of the other eye. Ten days later she complained of dimness in the left eye, and keratitis punctata was observed; fundus normal. Between the fourteenth and sixteenth weeks there was well-marked optic neuritis, but the cornea was clearer. During all this time, and until the twentieth week, atropine had been employed, but it was now left off although papillitis was still present, vision being normal. Ten weeks later she returned with tough adhesions of the iris around the pupil, V. 20-70, but no injection of conjunctiva. Atropine was used again for four weeks, and some fresh opacities appeared on the cornea. Fifteen months after the injury the cornea was nearly clear, the synechiae unchanged; still well-marked papillitis. The injured eye remained passive throughout. The case showed the importance of long-continued use of atropine. He also reminded the Society of another case he recorded last year in which complete recovery took place. In that case there was no optic neuritis.—The President agreed as to the importance of obtaining at an early period absolute exclusion of light, and as to the desirability of the continued and sustained use of atropine, so long as it can be borne without increasing the congestion of the eye, as is not infrequent in advanced stages. He could never forget one case he had to deal with. A child was brought to him within a few days of the occurrence of sympathetic ophthalmia which had attained a severe height. The eye was tense and bulging, and the cornea covered with opaque dots. The injured eye was much damaged and he excised it. Immediately after the excision the tension of the inflamed eye became normal, and after some weeks of severe iritis there was complete synechiae, the iris being in many parts so bulged as to encroach on the anterior chamber. After months of continued exclusion of light, and the use of atropine, the eye completely recovered, and a year later there was no trace of the synechiae, the iris being perfectly mobile. He was never more astounded or delighted at so complete a recovery. He agreed with Mr. Power as to the desirability of very early excision of the iris embracing the region of injury, and extending beyond it if possible, so as to detach all the points to which the iris might contract adhesion; and indeed, generally speaking, it is important to divide and destroy anterior synechiae.

Mr. Priestley Smith exhibited an improved form of the new registering Perimeter, described by him a few months ago in the *Ophthalmic Review*. In the original instrument the sight-object traversed the visual field in concentric circles. This method, though advantageous in certain cases—namely, wherever the limiting line of the field runs in a meridional direction—was not universally applicable. With the instrument as now constructed the field would be traversed either in meridians or in circles; it was thus more efficient,

as well as being simpler in construction. The axis which carries the quadrant had fixed to its posterior extremity a wooden disc or hand-wheel, balanced so that the quadrant would stand in any position without fixing. The chart was placed upon the posterior surface of the hand-wheel and rotated with it. Behind the chart was a bracket carrying a horizontal fixed scale, the divisions of which correspond with the circles on the chart; and when the instrument was rotated, whatever position the quadrant assumed, the corresponding meridian of the chart stood against this scale. In consequence of this automatic movement of the chart, the readings obtained on the quadrant were very easily pricked off upon it by a steel pencil held in the hand of the operator. The advantages of the arrangement were, that the chart was visible to the operator throughout, and indicated by its own position the exact position of the quadrant. Thus any particular part of the field could be at once brought under examination by bringing that point on the chart round to the scale, and re-examination could be made of any point at any time by placing the original chart in the instrument. The perfected instrument was in the hands of Messrs. Pickard and Curry.

Mr. J. E. Adams showed Drawings of a peculiar appearance at the Yellow Spot. The patient was a woman. There was a small slightly raised area in each eye; the nature of this was very uncertain; very probably it was a physiological peculiarity.

Mr. Couper exhibited an Ophthalmoscope, about a foot long, over an inch broad, and containing 140 lenses, which he found very convenient in estimating refraction. The construction of the instrument, which was very ingenious, cannot conveniently be described without a diagram.

Dr. Brailey made the following communications on Asthenopia:—1. The case of a delicate child, aged seven, in whom asthenopic symptoms were immediately and perfectly relieved by the use of a 4° prism, base in, divided between the two eyes. Both internal and external recti were absolutely weak, the latter apparently even more so than the former. There was no hypermetropia. 2. A case in which a prism, placed vertically, relieved symptoms of asthenopia. Correction by sphericals and cylinders gave partial relief, which was rendered complete by the addition of a prism of 3°, placed before the left eye with the apex down. The case was very like one reported to the Society by the author in 1881.

Dr. Brailey also read notes of a case illustrating the development of the condition known as Pseudoglioma. The disease began with an acute febrile attack, with swelling and redness of the lid, and proptosis and injection of the globe. Afterwards the eye became slightly shrunken; the iris-periphery was retracted; and a whitish reflex was visible from behind the clear lens. Dr. Brailey judged the case to be one of spontaneous suppurative hyalitis.

Memoranda on Eye Symptoms in Spinal Disease, prepared by Dr. W. R. GOWERS.

Of the ocular symptoms associated with spinal disease, two are of especial importance on account of their frequency—atrophy of the optic nerve, and the states of the pupil. Modern pathological investigation has rendered it improbable that these ocular symptoms are the result of disease of the cord. They are associated almost exclusively with degenerative diseases, and probably depend on a degeneration which is not structurally continuous with that in the cord. They are almost unknown in acute diseases of the cord, except when these follow, or are followed by, degeneration which runs

a practically independent course. Considerable interest will therefore attach to any cases that can be brought forward in which these symptoms were distinctly consecutive to an acute lesion of the cord. Optic nerve atrophy is associated especially with locomotor ataxy, and the association may be considered from the side of the ocular and of the spinal affection. In what proportion of cases of atrophy of the optic nerves can the signs of locomotor ataxy be detected? As the earliest and most constant of these signs, the loss of the knee-jerk may be conveniently taken as a criterion. In what proportion of cases of locomotor ataxy do the optic nerves undergo atrophy? It is not probable that a definite answer can be given to this question, because few cases of ataxy are followed to the end, so that the occurrence of atrophy cannot be excluded. But an approximate answer can be secured if the next question can be decided. When does atrophy of the optic nerves usually commence in the course of ataxy? The course of tabes may, for this purpose, be conveniently divided into three stages—(1) before there is any alteration in gait; (2) when the gait is distinctly ataxic, but the patient is still able to walk alone or with the aid of a stick; (3) when the patient is unable to walk without the help of another person. It is very important to know in what proportion of the cases of tabetic atrophy the change in the optic nerve commences in each of these stages. If the proportion of cases in which atrophy commences in the first stage is known, an approximate estimate of its total frequency can be formed from the number of cases in the second stage with and without signs of atrophy. Can any relation be traced, in a series of cases, between the occurrence of atrophy and the character of the spinal symptoms (pains, anaesthesia, etc.)? In what proportion of cases does tabetic atrophy affect one eye before and more than the other, and which eye is most frequently affected first? Does concentric limitation of the field always precede, or preponderate over, central amblyopia in tabetic atrophy? In rare cases there are unusual changes in the field of vision (e.g., temporal hemiopia). Observations on such cases are of especial importance, and so also are facts regarding acute failure of sight in this affection. Does the atrophy always progress to total blindness, or does it sometimes become arrested, and remain stationary for an indefinite time, as does the spinal affection? Can any instances of considerable and permanent improvement of sight in tabetic atrophy be brought forward? Observations and microscopical sections illustrating the pathological anatomy of tabetic and other allied atrophies are desirable, especially those which show the condition of the optic chiasma and optic tracts. In what respects does the optic atrophy of tabes differ from the optic atrophy sometimes associated with other forms of chronic spinal cord disease? When eye symptoms occur in general paralysis of the insane, is the case more likely to be complicated with spinal symptoms? States of pupil: The most frequent condition of the pupil associated with spinal disease is the loss of contraction to light, the pupil still contracting on accommodation (reflex iridoplegia, reflex rigidity of the pupil, Argyll-Robertson symptom). Erb has pointed out that, in these cases the pupil no longer dilates on a painful cutaneous stimulation (e.g., of the skin of the neck by a faradaic brush). Regarding this condition, information is needed on several points. Can this reflex dilatation be always obtained under normal circumstances? What is the most convenient and efficient means of obtaining it in regard to (a) place and (b) form of cutaneous stimulation? Is it true that there is always loss of re-

flex dilatation when there is loss of reflex contraction? The pupils are usually small in this condition, but not invariably, and are sometimes not circular. It is desirable to know whether any relation can be traced between the size and shape of the pupils and other symptoms. It is not uncommon to find, under the conditions in which reflex iridoplegia occurs, that the pupils contract under the influence of light; but immediately, the exposure continuing, dilate again to their former size, often with slight oscillations. Does this condition go on to loss of reflex contraction? In total paralysis of the internal muscles—ophthalmoplegia interna (Hutchinson)—the pupils are not usually small. What variations in the size of the pupils are met with in this condition? Regarding the association of these symptoms with spinal disease, it is desirable to know how frequently they are met with in locomotor ataxy and general paralysis of the insane, and in what other spinal diseases they occur. Both symptoms occur apart from spinal disease, and facts are needed as to the other conditions with which they are associated, and as to their relation to constitutional syphilis. Does ophthalmoplegia interna begin as reflex iridoplegia? Ophthalmoplegia externa has been shown to depend on nuclear degeneration. There is some reason to believe that reflex iridoplegia and ophthalmoplegia interna depend on a similar degeneration. Pathological observations on the nature of the lesion in these cases are much needed.

MIDLAND MEDICAL SOCIETY.

THE ordinary meeting of the above Society was held on April 4th, in the Medical Institute, Birmingham, Dr. Malins, President, in the chair.

Dr. Malins exhibited, with microscopical sections, two Atrophied Ovaries removed from a patient, aged forty. There had been no menstruation for six years, and great pain completely incapacitated the woman. Convalescence had been quite satisfactory.

Dr. Suckling showed a case of Paraplegia in a woman, aged twenty-five, which he considered to be hysterical. Owing to an attack of subacute rheumatism, a sudden rise of temperature occurred, attended with complete spastic paraplegia; but in twenty-four hours the rigidity passed off, and the patient was able to move about. There was ankle clonus and an increase of patellar reflexes on both sides, also analgesia. Electrical sensibility had been found to vary considerably, the responses being normal.

Mr. Hugh Thomas exhibited two very long Nails removed from the great toes of a woman, aged sixty-five. They had been allowed to remain uncut for eleven years. The right one measured five inches and a quarter, and passed under the four other toes. The left was three inches and three-quarters long, and lay over the other toes of the foot. The patient was unable to walk. After removal, the matrices on both sides were found to be healthy.—Mr. Thomas also showed a Placenta from a case of single birth, having a separate cotyledon imbedded in its membranes; attached to it was a rudimentary cord inserted into the maternal end of the umbilical cord, suggesting the former existence of another foetus. During the whole period of pregnancy there was persistent vomiting. No post-partum hæmorrhage took place.

Mr. Chavasse showed a child, seven years of age, upon whom he had performed Paracentesis Thoracis for Empyema by means of a double opening in the eighth intercostal space. The child was

lost sight of, but returned in four months with the drainage-tube *in situ* and the lung collapsed. In a fortnight after removal of the tube the wounds were closed, and the normal physical signs fully re-established.

Dr. Edgar Underhill (Tipton) exhibited eight small Phosphatic Calculi removed from a child, eight years old. The bladder had been examined for stone several times, but nothing could be detected with the sound. As circumcision did not altogether relieve the symptoms, Dr. Underhill made an exploratory incision into the bladder, and the stones were then readily detected by the finger and removed.

In a paper on the Administration of Parochial Medical Relief, Dr. Hickinbotham started by asserting that sickness was a most potent factor in producing and maintaining pauperism, and thus causing heavy rates. Therefore it was manifest that it would be an economical policy to use such means as would tend to prevent illness or shorten its duration. It was argued that to do this the best men, the best medicines, and the best appliances should be available in the Poor-law medical service. Three reasons were stated that deterred first-class men from accepting parish appointments: 1st, bad pay; 2nd, social disability; 3rd, harassing supervision. Dr. Hickinbotham considered that payment should be equal to that received by one of equal education and ability in the legal or other professions; that all medicines and appliances should be supplied at the cost of the parish; and that in large centres the appointments should be sufficiently valuable to demand the whole of the officer's time, as in the case of medical officers of health. Dr. Hickinbotham was not in favor of the permanent tenure of office, but thought that reasonable notice on either side should determine the appointment. It was thought that consultations should be held in obscure or difficult cases at the cost of the guardians. Referring to the management of workhouse infirmaries, an opinion was expressed that they would be best worked upon the hospital plan, with a senior and responsible non-resident and a junior resident staff of house-physicians and surgeons. Dr. Hickinbotham regretted the antagonism which often existed between boards of guardians and their medical officers, as also the attitude of the central authority, the Local Government Board, which, he said, was never marked by confidence or cordiality towards the medical profession.

The last ordinary meeting of the session was held in the Medical Institute, Birmingham, on April 18th, Dr. Malins, President, in the chair.

The President exhibited, with microscopic sections, an Hypertrophic Polypus of the Cervix Uteri; also an Ovarian Cyst showing the formation of daughter cysts. The tumour altogether weighed twenty-eight pounds.

Mr. Jordan Lloyd exhibited a specimen of Necrosis of the Patella, the result of using a peg leg in a case where the os calcis was previously diseased.

Dr. Edgar Underhill (Tipton) exhibited a simple form of Ovariectomy Trocar, which consists of a plain tube tapering to a point, sufficiently sharp to puncture any cyst, but not sharp enough to injure any internal organ. The openings are at the sides, and there are no clips of any kind. He had demonstrated its utility in a case at the Guest Hospital, Dudley, where a multilocular ovarian cyst was removed weighing seventy-two pounds. The usual clips he had found troublesome, often tearing the cyst-wall and allowing the escape of fluid into the peritoneal cavity.

Mr. Chavasse showed a Tongue removed by scissors for epithelioma. The hæmorrhage during the operation was so profuse that it was found necessary to open the trachea and suck the blood out of the patient's windpipe.

Mr. Hugh Thomas read the notes of a case of Uterine Hydatids accompanied by Icterus. The patient was an anæmic woman, aged twenty-six; the weight of the mass removed was three pounds and three-quarters; no post-partum hæmorrhage took place. With regard to the jaundice, the author thought it probable that a direct connection existed between the two conditions, caused by some undue pressure of the morbid mass upon the biliary apparatus, as when the uterus had been emptied a rapid convalescence took place.

Mr. Chavasse in a paper on Neurectomy as a Method of Treating Facial Neuralgia discussed the plans of performing the various operations that had been devised. Many instances were quoted, occurring in his own practice and those of other surgeons, in which the operation had resulted in long periods of relief; and, again, cases in which the painful manifestations were only subdued for a short time. The weight of the evidence showed that in certain instances neurectomy held out hopes of long or permanent relief from suffering when other means had proved ineffectual.

ACADEMY OF MEDICINE IN IRELAND.

A MEETING of the Pathological Section was held on Feb. 2nd, 1883.

Exhibition of Specimens.

Dr. C. F. Moore exhibited a living patient, a strong woman aged seventy-one, suffering from Molluscum Simplex. Neither her children, grandchildren, nor any relative had a similar disease. The growths commenced twenty-five years ago, without pain or injury to her health, in size varying from a small shot to that of a small grape; some sessile; some pendulous growing on the face, neck, hands, chest, and arms; none on the lower limbs.

Mr. Abraham showed microscopic mountings of new bloodvessels inosculating in granulation tissue among the meshes of a sponge skeleton after grafting.

Dr. Warren showed an example of Strangulated Obturator Hernia which had been discovered post-mortem.

Mr. Wheeler exhibited an Arm amputated for Compound Fracture, with extreme laceration; also a drawing of Erectile Tumour of the Forearm, removed successfully from a boy, aged sixteen, by excision; also a case of Congenital Deformity of the Hand, consisting in the absence of the little and ring fingers, with ribbing of the middle and index, the thumb being normal.

Mr. Stokes exhibited the Bladder of a patient who had been recently under observation in the Richmond Hospital, suffering from an exceptionally rare form of Penetrating Wound of the Bladder. The patient, a youth aged sixteen, employed in an ironfoundry establishment, was playing with a companion at vaulting over a pair of long forger's tongs. Failure attended one of his attempts to clear the instrument, and one of the long handles passed through the anus into the rectum a considerable distance. The boy fell, and the handle of the tongs was promptly removed by his companion. When brought to the hospital he was in a state of great collapse. His sufferings were extreme. There was some slight hæmorrhage from the rectum, and the urine being drawn off

was found deeply tinged with blood. On the second day all the symptoms were much aggravated. The abdomen became tympanitic and swollen, the pain agonizing, and there was great vesical irritability. On the third day the patient became delirious, in which condition he remained until released from his sufferings, seventy-four hours after the accident happened. The autopsy revealed a perforation of the anterior wall of the rectum, about an inch and a half from the anus. Here the instrument had passed into the bladder through the trigone and emerged at the fundus of the organ opening into the peritoneal cavity, in which there was a large quantity of purulent fluid. There were well-marked signs of extensive peritonitis. The author referred to the three somewhat analogous cases published by Mr. Prescott Hewett, Mr. Budee, and Mr. Bryant, giving the leading particulars of each and also to the cases mentioned by M. Houel and M. Joubert de Lamballe. The question, as to what is the chief factor inducing peritoneal inflammation in these cases, was likewise discussed, the author inclining to the belief—from the evidence afforded by several instances of vesical rupture, intra-peritoneal gunshot wounds of the bladder, and also the experiments of MM. Vincent and Murzel—that urine when first extravasated, and before any decomposition of its constituents takes place, is comparatively innocuous; and the practical deduction would be, provided no distinct contra-indication existed, the desirability in such cases of promptly securing a free exit for the urine by cystotomy or laparotomy, before the changes take place which, as a rule, lead to such disastrous consequences. In the case the author brought under the notice of the section, neither of these operations could be contemplated, owing to the extreme condition of prostration the patient was in when admitted into the hospital.

In the discussion which followed, Mr. Croly directed attention to the value which he assigned præcordial anxiety as a diagnostic symptom of ruptured bladder, a view which was not sustained by the facts of the case which Mr. Stokes recorded.

Microscopic Diagnosis of Phthisis.

Dr. Purser exhibited the Viscera of a man who had died of Phthisis. In the lungs there were tracts of dense fibrous tissue surrounding the bronchial tubes and pulmonary vessels, and extending to the neighboring portions of the pulmonary tissue. This was extensively consolidated by fibrous thickening of the alveoli. There were numerous tubercles, which had for the most part undergone fibrous changes. Caseation was not present to any great extent, but there was a large cavity due to this cause at the base of the right lung, and smaller cavities at both apices. The bronchial glands were indurated, and contained tubercles. Tubercles were abundant in the liver and spleen, both of which organs were amyloid. In this case the bacillus tuberculosis had been detected in the sputum five weeks before unequivocal signs of phthisis had been detected by the stethoscope.—Dr. Finney said the patient in question, when under his care, was the subject of amyloid disease of the liver. The point of greatest interest on that part of the case was the evidence it afforded bearing on the view of Schnupple and others as to where amyloid disease began. It was not amyloid degeneration springing from small arteries in the liver, and in which the whole enlargement was due to the liver cells being involved in the disease. Here the liver cells were pushed aside by the growing of the amyloid disease, the result of which was a sort of infiltration, which caused atrophy and de-

generation of the liver cells, and the destruction of their functions.—Dr. Walter Smith said this was the first case published in Ireland in which a microscopical diagnosis of phthisis had been made, and that five weeks before the ordinary signs of the disease could be detected by a skilled ear. He did not know whether they could hold that the converse proposition was true—namely, that the absence of bacilli argued the absence of phthisis. A gentleman came under his care with evidence of an inter-thoracic tumour. The evidences of that disease subsided, and the gentleman recovered; but he got a cough, began to expectorate a quantity of purulent fluid, and became thinner; and it was evident that there was mischief at the right lung. He (Dr. Smith) forwarded some of his sputum to Dr. Purser, who, having examined it, informed him that he had been unable to detect any bacilli in it. That was several months ago, and the patient had not since developed any symptoms of phthisis.

A meeting of the Surgical Section of the Academy was held on Feb. 9th, when Dr. T. E. Little narrated a case of Axillary Aneurism, for the cure of which he had deligated the subclavian in its third stage. The tumour had a traumatic origin. Great difficulties surrounded the diagnosis of the case, owing to an almost complete absence of pulsation or bruit in the tumour; nor could pulsation be felt at the wrist. There was a division of opinion among the surgeons who had been asked to examine the case; but ultimately the diagnosis of aneurism was arrived at. The operation selected and performed by Dr. Little was ligature of the third stage of the subclavian, the vessel being reached by an infra-clavicular incision. The result of the operation was most satisfactory.—Dr. Bennett dwelt on the difficulties that attended the diagnosis in this case, he being at one time of the opinion that the tumour was of venous origin. He subsequently, however, qualified this view. In deligating the first stage of the axillary artery he pointed out the advantages of keeping above, and not below the cephalic vein.—Mr. Stokes asked the author what were his reasons for selecting the infra-clavicular operation—one which, in Mr. Stokes' experience, was much more difficult than the operation above the clavicle. He also mentioned that the probabilities of finding the artery healthy were greater when distant operation was performed.—Mr. Porter considered the Academy indebted to Dr. Little for his excellent description of the operation. He believed the deligation of the first stage of the axillary artery was a more difficult operation than that of the third stage of the subclavian. He agreed with Dr. Bennett that the vein gave a great deal of trouble as a rule, and that the surgeon must with great caution pass either the aneurismal needle or the probe between them. Mr. Croly dwelt on the difficulty of the operation, mainly from the great depth of the vessel. It had been suggested, in order to facilitate reaching the vessel, to saw across the clavicle. The collapse of the aneurism after the operation was not a favorable sign. The case appeared to have many features of resemblance to that of an aneurismal varix. The occurrence of pulsation in malignant tumours he also mentioned.—Dr. Little, in reply, observed that to give some color to what Mr. Croly had said it appeared to him that the pulsation in the vein at the time was intrinsic. He gave his reasons for selecting the infra-clavicular operation, stating that the indications to keep as far as possible from the aneurism were not specially great, as the aneurism had a traumatic origin. He agreed with Mr. Croly that the collapsing of the aneurism on the application of the ligature was an unfavorable sign.

Mr. Kilgariff read the notes of three cases of Strangulated Hernia which had been operated on by him. The first was remarkable from the nature of the contents of the hernial tumour, consisting of the cæcum and a portion of the ascending colon in the cæcum having a free meso-cæcum and the protrusion having a complete sac. The second case was one of congenital hernia and presented many features of interest. The spermatic cord had a diameter of three-quarters of an inch, and was slung by a distinct and free mesentery. Again, the rigid, inelastic condition of the skin of the patient rendered the replacement of the testicle impossible and necessitated castration. In the third case there was a double stricture, the external consisting of thickened intercolumnar bands, and the second at the deep abdominal ring. The results obtained in these three cases were satisfactory. In the discussion which followed Mr. Ormsby, Dr. T. E. Little, Dr. Henry D. Fitzgibbon, Mr. Croly, the President, and Mr. Stokes took part. They drew attention to the after-treatment in cases of strangulated hernia, to the frequent possibility of reducing hernia after opening the sac without division of the stricture, to the possible connection of serous effusion in the sac and extreme tightness of the stricture, and to the desirability of making a high incision in the congenital form.—Mr. Kilgariff replied.

WIGAN MEDICAL SOCIETY.

THE first general meeting of the resuscitated Wigan Medical Society took place on April 5th at the Mechanics' Hall, King-street. The following were the office-bearers for the ensuing year:—President: Mr. W. Crowdsen Barnish. Vice-President: Mr. Elisha Monks. Treasurer and Honorary Secretary: Mr. R. Prosser White. An alteration in the time of meeting and amount of subscription having been passed, the President delivered an address upon "Recent Advances in Scientific Medicine." Two papers were read by Mr. Webster, one upon "Double Apical Pneumonia," the other "Excision of the Knee-joint." Microscopical specimens were exhibited by Mr. Barnish of varieties of bacilli. Mr. Jackson exhibited a recent specimen of traumatic perforation of the orbital plate of the frontal bone. There were present Messrs. Barnish, Monks, Williams, Webster, Brady, Withington, Jackson, Berry, Wood, White, E. H. Monks, Shepherd, and R. P. White.

SHEFFIELD MEDICO-CHIRURGICAL SOCIETY.

At the meeting of this Society held on April 12th, Mr. B. Walker, President, in the chair, Dr. Porter showed three cases of Fractured Patella to illustrate the good results that could be obtained from very simple treatment. One case had stood the test of fifteen months, and a second of nine months, in both of which union appeared to be either osseous or very fine fibrous. The third case had only occurred about five months, and the patient was not yet able to resume work; but as far as it was possible to judge of the result in so short a time, his leg promised to be as useful to him as the other cases shown. The same treatment had been adopted in each case—viz., back splint and foot piece, reaching well up the thigh, for three months, followed by gum-and-chalk knee-cap for two months longer. Dr. Porter dwelt particularly on the importance of firm compression at the very commencement, with a view to reduce the swelling, and ensure early apposition of the fragments.

Dr. T. H. Morton gave particulars of a case of Strangulated Umbilical Hernia successfully operated upon by him. The patient was a woman, aged sixty-four, and a reducible hernia, the size of a large orange, had existed many years. On March 7th it could not be returned by taxis, and on March 12th symptoms of strangulation appeared. Next day the operation was performed by dividing the upper edge of the ventral opening. Recovery was rapid. Dr. T. H. Morton also related a case of Hydrocele injected by Ergot. The patient, a strong man, aged twenty-nine, had first noticed a swelling eight years ago, probably induced by the saddle when riding. He had been tapped three times and an injection used once. On Feb. 24th, 1883, sixteen ounces of fluid were withdrawn by trocar, and iodine was injected. The patient came under notice again on March 25th with the fluid again collected. Eight ounces were taken away, and the treatment suggested by Mr. Walker was tried—viz., by injecting two drachms of the liq. ergotæ ext. (P. B.). Very little pain and but slight inflammatory action followed. There was no accumulation of fluid when seen on April 3rd.

Editorial.

ATTENUATION AND DESTRUCTION OF VIRUS.

AN important series of experimental investigations having practical bearings has been contributed to the *Lyon Medical* by Arloing, Cornevin, and Thomas. These observers arrive at the conclusion that certain forms of virus have their own way of reacting to various destructive agencies, so that without previous experiment it could not be predicted that this or that virus will be more or less affected by a given noxious reagent. The present course of investigations was made on the bacillus anthracis; the best virus was considered to be that extract obtained by powdering and squeezing the fragments of the symptomatic swellings of charbon, which had been treated with half their weight of pure water. This preparation contained microbes in the form of mobile rods, with or without free spores, and could be preserved fresh for some days if the external temperature were low, whilst if dried it remained active for two years, no matter what the temperature of the laboratory might be. The authors have found in conformity with previous conclusions, that dried virus was more resistant to destruction than fresh material; that the virulence of the agency is not necessarily related to the mobility of the organisms, for thymol and oil of eucalyptus are capable of attenuating the virus in forty-eight hours, without destroying the activity of the proper motion of the microbes. When the above-mentioned preparation was allowed to stand, it separated into two layers. The upper contained no organisms, effectual results were only got when inoculations were made with the lower layer. In certain cases no putrefaction occurred, even after the lapse of seven months, so that the symptoms observed in inoculated ani-

mals were not due to septicæmia. The juice of muscular tissue diluted with water did not preserve intact the virulence of the virus—this nutritive medium was therefore one mode of effecting attenuation. The rapidity, however, with which attenuation was effected varied; in some cases the virus had actually lost its virulence at the end of five days; other specimens continued active even after the lapse of eight, nine, or ten days. The power of the poison remained unaffected, notwithstanding exposure for three days to a degree of cold equal to that met with in the severest weather of the winter of 1880-81. The experiments made by submitting the organisms to various degrees of heat were varied and numerous; in their general outline they are corroborative of the conclusions drawn from his investigations by M. Chauveau, an account of which we presented to our readers in *THE LANCET* recently. When fresh virus was heated in sealed vessels to a temperature below 65° C., for ten to thirty minutes there was no modification of its activity—i.e., inoculations performed on guinea-pigs produced positive and rapid results. When the same virus was exposed to a degree of heat above 65° C., but below 100° C., the damage to the pathogenic activity of the organisms was more or less marked, according to the duration of the heat; the virus was rendered totally harmless if the heat were sufficiently prolonged. Inoculations performed on a series of guinea-pigs of the same age, size and sex (important points in experimental pathology, if they can be carried out), with the virus which had been heated to 65° C., for different amounts of time (fifteen, twenty, thirty, forty, and seventy minutes) were all successful in killing the animals at periods varying from twelve to forty hours after inoculation in an order which precisely corresponded to the duration of the exposure of the virus to the heat. When fresh virus was heated for two hours at 80° C., or for twenty minutes at 100° C., all pathogenic properties were lost. The same result was obtained at the end of two minutes if a tube containing the material were immersed in boiling water—an interesting occurrence, which was probably to be explained by the fact that impure water boils at a temperature above 100° C., whilst the conductivity of water is also greater than that of air, which was the medium in the other experiments. Curiously the addition of three volumes of boiling water to one of fresh virus left totally unaltered its pathogenic capacity. When the virus was desiccated a temperature of 85° C. for six hours was necessary to bring about a sensible attenuation of the activity of the virus; and a temperature of 110° C. for the same time was required for complete destruction of the pathogenic property. The authors have succeeded in preparing from the dried material, by submitting it to temperatures between 85° C. and 100° C., a series of attenuated preparations, by the aid of which preventive vaccinations were crowned with complete success. Dried virus required to be kept for

two hours instead of two minutes in boiling water, in order to completely destroy its virulence.

The study of the bacterial poison in connection with various reputed antiseptics is of much practical interest. To make comparisons between the various antiseptic agencies, their action was always allowed to go on for forty-eight hours, and five drops of the virus thus obtained were invariably the amount inoculated in animals to test the alteration of its activity. The difference between the degree of resistance of the fresh and dried virus was in this manner rendered very clearly. Out of fifty substances employed, thirty were powerful enough to destroy the pathogenic property of fresh virus, whilst only nine were capable of doing this with dried virus. Watery solution of carbolic acid 2 per 100, salicylic acid and nitrate of silver 1 per 1,000, sulphate of copper and boracic acid 1 in 5, corrosive sublimate 1 in 5,000, hydrochloric acid 1 in 2, saturated solution of salicylic acid in alcohol and the vapor of bromine, destroyed both the fresh and dried virus; watery solution of permanganate of potash 1 in 20, of chloral 3 in 100, of acetate of alumina 1 in 200, of benzoic acid 2 in 100, etc., only destroy the fresh virus. The authors were surprised to find that alcohol at 90° C., saturated alcoholic solution of camphor, the salts of ammonia, borate of soda, tannic acid, gaseous sulphurous acid, and many other substances, did not destroy the virulence of the poison after contact for forty-eight hours. These conclusions are remarkable. It would appear that we are quite unable to predict from previous knowledge of the chemical power of various agencies whether such agencies will prove as powerful in destroying bacteria as we might with some reason anticipate. For example, it will be seen that a very dilute solution of corrosive sublimate seems to be quite as effectual as a strong one of hydrochloric acid. It was the above results which led the authors to make the statement already alluded to concerning the peculiar mode of reaction of certain kinds of virus to various agencies. Again, a strong caustic like chloride of zinc may fail as a means of destruction when the vapor of thymol may succeed. Many experiments made with fresh and strong preparations of peroxide of hydrogen failed to substantiate those made by MM. Best, Regnard, Nocard, and Mollereau. Arloing found that oxygenated water capable of setting free ten volumes of oxygen on decomposition was no more able to modify the activity of the charbon virus than ordinary water after contacts varying from four to ninety-six hours. The above researches are of great suggestiveness; they seem to point to a way out of the difficulties which surround the treatment of persons already the subjects of infectious diseases. The destructibility of the activity of bacteria once introduced into the animal organism, either by attenuation or complete annihilation, if such be possible, has until recently appeared to be altogether beyond our ken, from the simple no-

(12)

tion that it was to be feared that agencies capable of effecting their modification could only act at the price of at least corresponding damage to the tissues of the animal affected. These latest experiments hold out a hope that our therapeutical measures may not always be in vain, and even that apparently trivial means may in this regard be as powerful as seemingly more efficient methods. It would seem that here, as elsewhere, knowledge may be more powerful than power. Further, the proper protoplasm of animal bodies in one way or other by some of the various processes originating in it, may be in an apparently accidental manner really the efficient cause of the termination of acute infectious diseases, either by introducing the necessary factor for the complete attenuation of the acting virus, or by lending support to the activity of the poison. In some such way the considerations arising from these recent researches may lend a helping hand in the elucidation of many important pathological processes.

THE DEBATE ON DIABETES.

WHATEVER its shortcomings in other respects, the recent debate on the Pathology of Diabetes at the Pathological Society must be credited with having cleared the ground of much that was uncertain and doubtful, and indicated the path in which researches into the causation of the disease may in future be followed with advantage. As Dr. Dickinson pertinently observed, diabetes must have a pathology; but the question at issue is whether the primary condition is a chemical fault, or due to lesion of the cerebro-spinal system. Dr. Dickinson, as is well known, is in favor of the latter view, and he bases his position, first, on the fact that the disease is persistent, notwithstanding entire changes in the environment of the individual, and the suddenness of the onset, generally following on some intense mental disturbance, such as grief, anxiety, fright, etc.; secondly, on the existence of certain lesions he had discovered in the brain. With regard to the first proposition, we do not think the persistency of a disease necessarily proves that it depends on changes in the permanent structures; indeed, the most persistent of disorders are generally those which are acknowledged to take their origin from a morbid condition of the blood, and only lead at last after long continuance to definite local lesions. Nor can the fact that the disease sets in suddenly be taken as evidence of its arising from a change of structure, nothing being more likely to produce chemical aberrations than violent emotions acting through the nervous system. With regard to the existence of well-defined nerve lesions in the disease, Dr. Dickinson's position is very generally questioned. It is not asserted that no such lesions are to be found, but that they are not peculiarly associated with diabetes. Thus, Dr. Hale White stated that out of twenty-three post-mortem examinations made at Guy's Hospital on diabetic subjects, no

changes in the nervous centres were detected; whilst he brought forward specimens from subjects in whose urine no sugar had been found which exhibited the special lesions. Dr. Frederick Taylor's evidence as regards the result of post-mortem examinations at the same hospital was much to the same effect. He considered the majority of his specimens healthy, and only one of them deviated much from the usual standard. The experience of the London Hospital is very similar to that of Guy's. Dr. Stephen Mackenzie, in one of the most effective speeches of the debate, in which he discussed fully the various changes found in the different organs of the body after death in diabetes in relation to cause and effect, stated that in fourteen cases in which the nervous system was examined no changes were met with; in six cases slight peri-ganglionic vascular dilatations were found, but it was doubtful how far they were due to the mode of preservation. Dr. Seymour Taylor, of St. Thomas's, had failed to meet with the vacuolations described by Dr. Dickinson; he spoke of the difficulty of successfully hardening and mounting specimens of the nervous system for microscopical examination, and was inclined to believe that many of the appearances regarded as morbid might be due to the method of examination. This point the committee that is to be appointed to examine the specimens and inquire into the methods of preparation employed by the exhibitors will no doubt definitely settle. If this committee should report that the changes observed by Dr. Dickinson are not due to his method of examination, but are manifestly morbid, then the connection of the disease with distinct nervous lesion must be again discussed with regard to the question of the change being a primary one or a result of the disease.

But if we have to discard the view of an originating nerve lesion, what other hypothesis can be advanced? Chemistry, or at least modern chemistry, has as yet advanced no definite theory; but it has not been idle, and those who have followed this line of research have collected many valuable facts, from which no doubt important conclusions will in time be drawn. Indeed, we are surprised that they have not already attracted more attention. Hardly a speaker alluded to the very important investigations, chiefly based on chemical research, that have been carried on by Dr. Pavy for many years, and which have led him to the conclusion that the phenomenon of diabetes is dependent on an afflux of blood, not properly venous, to the liver, and that this afflux is brought about by vaso-motor paralysis. Our space is too limited to state at length the experiments on which Dr. Pavy has founded his view, and we must refer our readers to his Croonian Lectures of 1878 and an abstract of his paper on the Physiology of the Carbohydrates, read this year at the Royal Society. This vaso-motor paralysis depends of course on nervous disturbance, but it is referred to the sympathetic rather than the cerebro-spinal system. Nor need

it necessarily have origin in the large ganglia; there may be intrinsic conditions of the liver tissue or in the chylipoietic viscera generally sufficient to produce it. When the degree of vaso-motor paralysis is slight, we have a mild form of glycosuria; with a greater degree, the more acute and persistent form of diabetes. Dr. Ralfe also speaking from the chemical side of the question, contributed some original material to the debate. He especially insisted on distinguishing between the forms of diabetic coma, and pointed out that the ordinary form was generally the termination of long-standing cases, whilst the acute variety, attended with marked and peculiar symptoms, and which was infinitely rarer, was rather an accident than a natural feature of the disease, and was generally associated with anomalous and irregular forms of glycosuria, and that in these cases a fatty condition of the blood, the result of a chemical change in its composition, is most frequently met with. He also laid stress on the highly acid condition of the urine in diabetes, and hinted that this might furnish a clue to the chemical changes taking place in the blood.

In short, the general conclusions to be drawn from the debate are that diabetes is not associated with any definite structural lesion of any organ; that it is due to disturbance of functions of the liver, brought about apparently by a peculiar condition of the circulation in that organ; and that this condition, vaso-motor paralysis, can be induced experimentally in the living animal. The question was left open whether in diabetes this vaso-motor paralysis is caused directly by disease of the sympathetic or indirectly by the action of some chemical fault originating in the chylipoietic viscera, or in the blood itself.

ON THE TESTS FOR ALBUMEN AND SUGAR IN THE URINE.

DURING the past six months we have published numerous contributions relative to the most suitable reagents and best methods for the detection of albumen and sugar in urine. The interest that has been excited by this question is an evidence of the revived appreciation of questions of pathological chemistry which seems to be gradually setting in. The new tests, or, to speak more accurately, old tests resuscitated, have been introduced with a view ostensibly of facilitating urine-testing at the bedside; in short, to do away with the cumbersome paraphernalia of spirit-lamp and bottles of nitric acid, copper solution, etc. If the introducers could have stopped short at this laudable intention, the student and practitioner would have been duly grateful; but unfortunately so many abstruse chemical and physiological questions had to be considered that a general bewilderment has been the result. So much has this been the case that the Clinical Society has appointed a committee to report on the tests for the detection of albumen and sugar that have been brought under

the notice of its members during the past session. The report will no doubt be an exhaustive one, and, to those unacquainted with the literature of the subject, interesting; but it can hardly add much that is new, since students of physiological and pathological chemistry are already fully acquainted with the range and capabilities of the so-called new tests, allusions to which will be found in most of the foreign journals and the text-books devoted to this question.

To take the subject of albumen first, it will be found that all the new tests are more or less applicable for the detection of proteid substances in urine, whilst no one of them especially indicates the presence in its unaltered form of serum albumen. To detect this it is necessary to apply heat, since this body coagulates at temperatures between 73° and 75° C. But not only do these new tests fail to distinguish serum albumen from other proteids, but most of them likewise give a reaction with other bodies met with in the urine, as mucin, peptone, parapeptone, and the like. It is probably owing to the precipitation of these substances, in some instances, that the new tests have laid claim to extreme delicacy. Again, some of the introducers have stated that the tests will discover traces of albumen after it has been separated by coagulation by heat, thus showing that their test is more reliable than the "coarser" method of heating for the detection of minute traces. This assumption is based on a fallacy, since it is extremely difficult to separate all the albumen by heat, a small portion always coming through the filter with the filtrate. The Germans have been aware of this fallacy for some time, and give minute directions as to the individual and complete separation of mucin, peptone, and albumen, in all cases where an exact examination is called for.

The picric acid test seems to us the best of the new reagents. It is certainly more delicate than nitric acid, as it is more manageable and portable, whilst it has the advantage of being made available for sugar-testing. One objection raised against it—the bulk of its solution—is really no practical disadvantage, since, if employed, as Dr. Johnson suggests, by carrying a few grains of the substance in bulk in a small box, and dissolving a pinch in half a wineglass of water, the solution is readily made at the bedside of the patient. Picric acid, however, like most other reagents except heat, precipitates every variety of proteid substance, as well as mucin, parapeptone, albuminose, and urates if present in excess, and these have, therefore, to be identified by distinguishing reactions. In this respect, however, picric acid is equally at a disadvantage with nitric acid and many other reagents. If at the present moment we were asked what test, after all, we should rely on for the detection of serous albumen in urine, we should unhesitatingly answer, Heat. If an ordinary test-tube be filled nearly full with filtered

urine, and the upper end be heated whilst the lower portion remains cold, the minutest trace of albumen will be revealed by the haze given in the warm portion, which shows up in strong contrast with the clear cold portion. A drop of acetic acid or ordinary vinegar if at a patient's house, will determine if the haze be due to phosphates, whilst neither mucin, parapeptone, nor urates are precipitated by heat. Picric acid, ferrocyanide of potassium, or the mercuric tests may then be used as confirmatory.

Passing on to the tests for sugar, we are inclined to think that Dr. George Johnson's application of picric acid with liquor potassæ for the detection of this substance in urine is likely to be widely adopted for clinical purposes, especially his method for quantitative determination. His valuable communication on this subject to the Clinical Society has not had full justice done it, owing no doubt to the controversy raised with regard to the action of picric acid in albuminous urines. Dr. Johnson's saccharimeter is an exceedingly neat instrument, and the determination can be rapidly effected. We know of no process so speedy and convenient, whilst there is no doubt that its results are trustworthy. It is just the process for work in the wards, since it can be carried out then and there at the bedside of the patient, without having to refer the urine to the chemical laboratory, or to wait twenty-four hours, as is the case with the fermentation process. Dr. Oliver's application of the indigo carmine test is likely to prove useful to the busy practitioner at the bedside, though for reasons dwelt upon recently it cannot be relied upon as proving beyond doubt the presence of glucose, since it gives reactions with all the carbohydrates. In all cases, therefore, it would be necessary to determine the nature of the carbohydrate by means of the copper test.

In conclusion, we venture to hope that the discussions these various tests have given rise to will create an interest in that hitherto much neglected branch of medical science—pathological chemistry. Paracelsus ridiculed the physicians of his time for remaining content with the mere inspection of the urines of the sick, and for making no attempt to become acquainted with their real nature by submitting them to analysis; but the present generation have been as negligent as their predecessors, since they have not only not availed themselves of much of the really good work already done in this direction, but are apparently ignorant that such work has been done. For its own credit we hope that the report of the Committee of the Clinical Society, even if it can add nothing fresh, will do full justice to the past work in this field, and also clearly indicate the lines of future research.

THE appalling statement has been made that over six thousand women die yearly in the United States from attempts to destroy unborn children.

BOVINE AND HUMANIZED LYMPH IN THE UNITED STATES.

Amongst the subjects dealt with in the Sixth Annual Report of the Board of Health of the State of New Jersey is that of small-pox and vaccination, the Board having submitted a series of questions to certain practitioners having special experience in, and acquaintance with, the subject. One of these questions was whether the use of bovine lymph should supersede the use of humanized lymph. As to this Dr. Thomas F. Wood, of the North Carolina Board of Health, regards the reasons in favor of the arm-to-arm practice as outweighing those in favor of the use of lymph direct from the calf, its effects being milder, more uniform, and more convenient than those attending the use of bovine lymph, and he refers to the experience of Great Britain as proving the "excellent results" following on it. Dr. Ezra M. Hunt, of the Jersey State Board, after discussing the subject very fully, does not admit the necessity of the use of bovine lymph by reason of the loss of any original power in the Jennerian lymph, but he considers that since the use of such lymph does away with any cavil as to the possibility of the transmission of human diseases, and since the calf enables us at almost any moment to secure an almost unlimited supply fresh and ready for use, calf lymph must be regarded as an addition to the available stock of such advantage as to be of the utmost importance. This latter consideration would necessarily have special weight in America, where, vaccination not being compulsory, exceptional demands are liable to be suddenly made on the lymph-supply in moments of emergency. Dr. E. L. Griffin, President of the Wisconsin Board of Health, is not of opinion that it is either necessary or wise that bovine lymph should supersede the use of humanized lymph. Both he regards as protective, indispensable, and, with wise safeguards in their selection and use, also safe. What he most recommends is humanized lymph of only a few removes from the heifer, and when this lymph is used he knows of no data by which the superiority of the one over the other can be determined. Dr. E. J. Marsh, President of the Board of Health of Paterson, gives the result of his lengthened use of humanized lymph up to 1873, such use having been in every way satisfactory, as regards alike its protective power in the face of two epidemics, its safety from anything but trivial injurious results, and its success in taking effect. Since that date he has used bovine lymph, and he continues to use it for three reasons:—In the first place, much has lately been written about the danger of transmitting syphilis through humanized lymph; a possibility of degeneration of the Jennerian stock had presented itself to his mind; and, finally, patients ask for bovine lymph because its use has become fashionable. The results of calf-lymph have been the production of more severe local and constitutional symptoms, in-

flammatory action in a few cases having run so high that the vesicle sloughed out *en masse*, leaving a deep ulcer. So also the only case of post-vaccinal erysipelas he has met with has occurred after using bovine lymph; he does not, however, think this was due to the character of the lymph, but was solely "the result of traumatism." Bovine lymph should, in his opinion, be retained because the protection it affords is certain, and on this account it can be used in some cases where prejudice would interfere with the best humanized lymph. So also one of the prominent advantages it affords is the ease with which the supply can be made to meet any demands. On the other hand, humanized lymph should also, he says, be retained, because it is protective against small-pox, because with care it can be guaranteed as safe in regard to the syphilitic poison, because it can be propagated by any medical practitioner himself, and lastly, because of its comparative cheapness.

These views, based as they are on wide experience gained in a country where both humanized and bovine lymph have had a long period of probation, come in aptly, as proving the wisdom of our own Government in this matter. The central department now issues bovine lymph to those who ask for it, but it does so under limitations which clearly show that, whilst willing to meet a public demand and to provide even for the prejudices of the population, it has lost none of the confidence which it has all along expressed in the protective value of lymph transferred from arm to arm, a confidence which is fully borne out by the marked and convincing results which have followed on the vaccination with humanized lymph of the nurses and other officers in our large small-pox hospitals.

Reviews and Notices of Books.

The Sanitary Contrasts of the British and French Armies during the Crimean War. By Surgeon-General T. LONGMORE, C.B. 8vo, pp. 31. London: Griffin & Co. 1883.

THIS work of Mr. Longmore's brings before the profession, and especially the military branch of it, a very concise and interesting view of the sanitary condition of the French and British troops during the campaign of 1854-56 in the Crimea, the remarkable differences in the two forces, and the causes to which these were attributable. Though upwards of a quarter of a century has elapsed since the termination of that war, and though much has been written regarding it, we are not aware of any work which brings into contrast the state of the allied armies from a sanitary point of view, and we are therefore pleased to find this desideratum so ably supplied by one entitled to speak on the subject with great authority. The necessity for such a work is all the greater owing to the misleading remarks by Mr. Kinglake in his recent volume, in which, as Mr. Longmore justly remarks, "avoiding uglier designations, that might grate upon the ears of his readers, he

applies the euphemism of 'winter troubles' to the ghastly sacrifice of lives and inexpressible suffering among the troops, the mere recollection of which still causes a shudder to those who were familiar with the tragic scenes that took place, day after day and night after night, in that part of the army which was encamped in the front before Sebastopol in the winter of 1854-55." Mr. Longmore has brought together the statistics of mortality in the two armies, divided into periods of four months from September, 1854, to April, 1856. It would be impossible in the space at our disposal to enter into all the details thus given; we shall therefore merely note, with regard to the British army, that during the first winter the mortality among the troops was frightful, amounting in six months to one third of the average strength, while in the second winter it was so much reduced as to be little above what would have occurred had the men been serving in England. In the French army, on the contrary, the death-rate in the first winter, though high, did not approach to anything like that of the British, but in the second winter it was nearly one-half higher than in the first, and more than thirteen times that of their allies during the same period.

Mr. Longmore discusses the circumstances which led to the fatal sickness in the British army during the first, and its remarkably healthy condition during the second, winter, and to the comparatively healthy state of the French army during the first, and its increased sickness and mortality during the second, period. The condition of the British army in the first winter he attributes to our neglect of the old maxim, "to be prepared for war in time of peace," and to our disregard of even the elementary teachings of sanitary science. Our troops, whose general health had been impaired by their stay in the unhealthy valleys of Bulgaria, were landed in the Crimea, "without tents or cover, every one lying and sleeping on the damp ground; and subsequently the hardships, privations, and suffering of the winter seige, the exposure to cold, and the loss of rest in the trenches and on picket duty at night; the ill-suited clothing, the tight coats, and the closely fitting trousers of that time; the want of fuel; the want of means of personal cleanliness; the excessive overwork, increased, as the numbers lessened, among those who remained; the want of adequate nutriment, all hygienic rules outraged in respect to sufficiency, quality, variety, and cooking of the food—the rations consisting almost exclusively, for a considerable time, of salt meat and biscuit, without vegetables." With regard to the medical arrangements, he observes: "Had the recorded experience and recommendations of army surgeons who had served during the Peninsular wars been acted upon, there would have been an organized army hospital corps, suitable field hospital establishments, suitable field hospital transport, adequate in amount and ready at call for service; but there were none of these when the campaign commenced." The French, on the contrary, "started with the necessary equipment for service in the field; officers and men were familiar with the use of it, and duly estimated its importance." They had their *tentes d'abri*, their ambulance wagons, their fur overcoats, their bakeries, their well-organized transport, and the troops generally were well instructed in the practice of cookery. These differences sufficiently account for the marked contrast in the health of the troops during the first winter. To what, then, was the remarkable change in their relative condition due in the second winter? Mr. Longmore considers it very easily explained by the extraordinary efforts made by the people of England to retrieve the disasters

of the first winter and to obviate their recurrence: the abundant supplies of food and comforts of all kinds, of clothing, shelter, and transport, which were provided without stint; the improved conservancy of the camps, and the strict enforcement of sanitary regulations. But while this was being done for the British Army, the French began to suffer from neglect of these very matters. "The French in the second winter had got into circumstances very similar to those of the English in the first winter, while there was neither the enthusiasm on the part of the French nation nor the pecuniary means which had been called forth on the British side to effect a similarly favorable change in the sanitary condition of the French troops. Neglect of the advice of those who were competent to advise on the means necessary for preserving the health of the troops, and the authority of the intendants, who were quite incompetent to give directions on hygienic matters, led to the development of the scurvy and typhus which broke out among the French troops, to the constant increase in virulence of these diseases, and at last to their diffusion in such overwhelming proportions that all available resources were powerless to cope with them."

Mr. Longmore has done good service in bringing to notice the special circumstances which exercised so disastrous an influence on our army in the Crimea, and the measures which were adopted to restore its health. They are well deserving of study by all who take an interest in the welfare of our troops, and especially of those who are responsible for the efficient organization of our army and of those on whom the practical application of the measures devolve. The recent campaign in Egypt, though it showed nothing so disastrous as that of the Crimea, found us in the old condition of unpreparedness to take the field. On this, as on most previous occasions, the want of an organized and efficient transport seemed to be at the root of all the sufferings to which the men were exposed, and to an efficient organization of this branch of the service it is manifest the attention of authorities ought to be immediately directed. We observe that Mr. Longmore calls attention to the unfairness with which Mr. Kinglake has treated the statistics of the French army in the Crimea, published by the late Dr. Chenu. We are not the least surprised at this after the exposure which Sir John McNeill, whose death at a ripe old age occurred very recently, made of the misleading statements by Mr. Kinglake on the subject of the Crimean Commission, and of the "ludicrously inadequate" cause assigned by him for the fatal privations suffered by our troops in the Crimea.

Health Lectures for the People. Third Series. Delivered in Edinburgh during the winter of 1882-83. 8vo, pp. 218. Edinburgh: MacNiven & Wallace. 1883.

THIS volume consists of the lectures delivered at the request of the Edinburgh Health Society during the past winter. The object of the Society is "to promote by all the means in its power attention to personal and domestic cleanliness, to comfort, self-denial, temperance, and the laws of health generally." The subjects treated in the present volume are: Ventilation, Physical Exercise, Brain Health, Domestic Economy as regards Food and Cookery, the Ear in Health and Disease, the Eye the Organ of Vision, Minor Ailments and their Treatment, Nursing the Sick, and Sanitary Law and Administration. These lectures of course vary much in quality. Some of them appear to be over the heads of the class for whom they are

intended, while others are remarkably well adapted to promote the objects the Society has in view. In the latter group may be noted Dr. Douglas MacLagan's clear, intelligible, and practical lecture on Ventilation, Miss Phoebe Blyth's on Food and Cookery, Dr. Jameson's on Clothing and Household Arrangements, and Dr. Halliday Croom's on Nursing the Sick. The concluding lecture, by Mr. W. C. Smith, of the Scottish Bar, gives an interesting summary of the state of sanitary law and administration in Scotland, with some suggestions for its improvement. The lectures are also published separately, at a very low price, for circulation among the people generally, and appear likely to direct their attention to the most important subjects bearing upon the preservation of health.

Warming and Lighting the Dwelling; their bearing on Health and Disease. By JOHN ANGELL, Science Master, Manchester Grammar School. London: Heywood. 1883.

This also is one of a series of Health Lectures for the People, and is published at a nominal price by the Manchester and Salford Sanitary Association. It was illustrated by experiments of a popular nature showing the effects of respiration and combustion on atmospheric air, and was apparently intended for a more highly educated class of persons than those to whom the lectures at Edinburgh were addressed. We cannot doubt that the labors of these Societies to spread a knowledge of sanitary principles among all classes of the people will have a beneficial influence in promoting the public health and in diminishing the amount of preventable disease. From their low price they are well suited for general distribution.

Principles of Health in Childhood, Manhood, and Old Age. By LOUIS KING, M.R.C.S. 8vo, pp. 185. London and Bath: Hamilton & Co. 1883.

THE object of this book is much the same as that of the Health Lectures already noticed. It directs attention to errors in ventilation and drainage of houses; it discusses the principles on which the diet and general management of children and aged persons should be conducted; and it concludes with instructions respecting the immediate treatment to be adopted in accidents and emergencies. The introductory chapter on Physiology might, in our opinion, have been advantageously omitted, and the other portions would bear judicious condensation. The work altogether is too diffuse, although there is, no doubt, much good advice in it, especially with reference to the management of children. A good index would add greatly to its value.

Lectures on Medical Nursing. By Dr. J. WALLACE ANDERSON. Glasgow: James Maclehoose & Sons. 1883.

A Manual of Nursing, Medical and Surgical. By Dr. C. J. CULLINGWORTH. London: J. & A. Churchill. 1883.

Notes from Sick Rooms. By Mrs. LESLIE STEPHEN. pp. 52. London: Smith, Elder & Co. 1883.

THE numerous additions that have of late been made to the literature of nursing are a natural outcome of the greatly increased interest that the subject has excited, and are the direct results of an attempt to extend a knowledge of the true principles of the nurse's art.

Dr. Anderson's little work provides an admirable account of medical nursing, and is in many respects the best manual we at present possess upon the subject. The book is carefully written, the style is clear and attractive, and the arrangement of the matter is admirable. Dr. Anderson has succeeded well in giving just that amount of information of the commoner phases of disease that every medical nurse should possess who wishes to take an intelligent part in her work. In supplying this information, he has with equal care avoided providing too much of that "little knowledge" of medicine which to many nurses "is a dangerous thing." In Lecture IV., for example, the author gives a simple and lucid account of the process of digestion, and especially points out those practical lessons that can be drawn from a knowledge of the process. He then deals with the comparative digestibility of various articles of diet, and concludes with a thoroughly practical account of the cooking of food, and of its administration. At the end of each lecture is a number of questions which deal with the principal points discussed in that lecture, and the book concludes with a glossary of the commoner medical terms; which although scanty, is yet well arranged.

Dr. Cullingworth's manual, which is of smaller size than the preceding, deals with the whole subject of medical and surgical nursing, and is therefore a somewhat more ambitious volume. From the small amount of space that Dr. Cullingworth has allowed himself for the discussion of the whole matter, it follows that his descriptions are much abbreviated, and are apt to be a little bare. The author limits himself rather to an account of the appliances used in medical and surgical nursing, and has little to say of the needs of such appliances, and the reasons for their use. The manual, however, is, so far as it goes, simple, practical, and precise, and may be accepted as a trustworthy guide to the knowledge of the technicalities of nursing. Woodcuts are given to illustrate some of the commoner dressings and appliances, and add to the value of the book.

We have read Mrs. Stephen's work with much pleasure, and can cordially recommend it not only to the relative who is in charge of a sick person, to whom perhaps it is more particularly addressed, but also to the trained nurse and to the medical attendant. The book is distinctly clinical in character, and could not have been written by anyone who had not enjoyed ample experience of the requirements of patients. It does not deal so much with abstract questions of nursing as with the thousand apparently trifling matters which go to make or mar the comfort of the sick room. Nowhere else, perhaps, is it so true that "evil is wrought for want of thought," and the kindest, most self-devoting of relatives, may fall into little errors of omission, or still more frequently of commission, which are intensely trying to the delicately organized patient. We may mention such subjects as the making of the bed, "crumbs," the mode of changing the linen, the management of waterproofs and handkerchiefs, the mode of washing a patient and doing her hair, as examples of the kind of information which is imparted with graphic detail in the book. From the preparation of food and the mode of helping a patient to take it, to the management of visits from friends and the patient's fancies, all is carefully considered, and numerous hints imparted, many of which the most experienced of us will be glad to receive. The medical man is out of place as a nurse, but he should be learned in all that relates to the art of nursing, if his patient is to be well cared for. It is, therefore, a great advantage when a lady of refinement gives us, as

Mrs. Stephen does, the benefit of an experience evidently personal and practical, which is conveyed in simple and effective language.

Mechanical Exercise a Means of Cure Being a Description of the Zander Institute, London.

Edited by the Medical Officer to the Institution.
London: J. & A. Churchill.

THE subject of exercise, both as a means of physical development and as a method of cure, while it has of late years come to bulk largely not with medical men alone, but also with the public, and especially in the minds of those who have the care of children and young people, has not, we believe, received the amount of attention that its importance deserves. Regulated exercises have from time immemorial been found to be of great value for the establishment and maintenance of physical vigor in those already sufficiently robust to profit by them in the somewhat rough-and-ready manner in which they have hitherto been applied; but they have occasionally been brought into discredit from the fact that delicate organisms seemed to be overstrained. The great difficulty has been to apply exercise in such a manner that it could be adapted not only to the removal of physical defects and the strengthening of weak parts, but also to be able accurately to graduate the force in proportion to the strength of the patient. It is claimed, and with good show of reason, that in Dr. Zander's system these ends have been attained. The little work before us is a description of the Zander Institute, recently established in London. It gives a brief account of the different machines, their action, and the cases in which they are likely to be found most useful, including also notes of a few cases of chronic rheumatism, stiff and deformed joints, partial paralysis, spinal curvature, constipation, etc., etc., that have been successfully treated. The machines are divided primarily into two classes—(a) those for active exercises, in which the patients themselves do the work, and (b) those for passive exercises. The latter are worked by a gas engine. The amount of resistance can in each case be carefully regulated by means of a movable weight placed on the levers, and thus the danger of overtaxing the strength is removed, while the resistance can be increased in proportion as the muscular power increases. The adaptation is in many instances extremely ingenious, and we anticipate that the more the system becomes known the more widespread will its application be found. Dr. Zander began his experiments some twenty years ago. His first subjects were the pupils of a large school, and he found even in the most delicate children, not only an increase of strength and weight, but an improvement in general health and spirits. It is clear that an institution of this sort can work successfully only by gaining the confidence of the profession, and the directors seem to be aware of this, for it is stated that they consider it particularly desirable that patients should before commencing a course of treatment consult their own doctor, and if they choose they can remain under his sole care all the time. Each patient is thoroughly examined at least once by the medical officer of the institution, and to medical men sending patients every facility for guiding and watching their course is afforded. Thus while the objects of the Zander Institute are in the main curative, it seeks also to enter the sphere of preventive medicine by affording to those whose occupations condemn them to a sedentary life the means of obtaining safe and regular exercise. We therefore heartily commend it to the attention of the profession.

The book is neatly got up and the facts are clearly and tersely stated. The drawings give a good idea of the machines, but those who are interested in the subject should visit the establishment and test for themselves the actions of the various machines.

Revue Mensuelle des Maladies de l'Enfance. Avril, 1883. Paris: Lauwereyns.

THE April number of this journal, which appears to have the collaboration of many eminent French physicians, contains original articles on the Treatment of Congenital Phimosia by Preputial Dilatation, on the Headaches of Young People, and on the Treatment of Infantile Maladies by the Waters of Bourbonne-les-Bains. Of these, the last, by Dr. Mercier, is perhaps the most important and deserves further consideration. We are disappointed not to find detailed statements as to the modes of application of the Bourbonne treatment and of the special indications for particular methods. There is also given a classified synopsis of recent contributions on children's diseases, by French, German, English, and American writers, and concerning this admirable section of the journal, we can only offer the criticism that some of the summaries are rather meagre. From the reports of societies, it is clear that M. Parrot's view as to rickets being solely a transformation of congenital syphilis, scarcely commands any more acceptance in Paris than in London.

Les Hystériques : Etat Physique et Etat Mental; Acts Insolites, Delicieux, et Criminels. Par le Dr. LEGRAND DU SAULLE. J. B. Baillière et Fils. 1883.

PROBABLY all physicians would agree with the opinion that hysteria as we know it and hysteria as witnessed by the French is very different, not perhaps so much in nature as in degree. To the English student of medicine it would almost certainly be a great waste of time to read a French work on hysteria, we mean only so far as concerns the actual practice of physic in England. The present work is one of considerable size; the matter is of a readable kind, well digested, and evidently comes from the mind of a physician well versed in the study of mental and nervous disease. Nothing else could be expected from an observer of Legrand du Saulle's experience and standing. The first chapter considers sufficiently all the alleged factors in the etiology of the disease. The opinion is stated that the neuropathic disposition is the most efficient element in the causation. The author does not seem inclined to regard flexions and versions of the uterus as having much to do with the origin of hysteria. We fully endorse this opinion. The various corporal manifestations of the complaint are amply dealt with in the second chapter. Hypnotism, as observed in hysterical patients, is considered in the next section, and Charcot's contributions to the theory of the subject, the dominant idea of which is the hyperexcitability of the neuro-muscular apparatus, receive a prominent place. Disorders of the mental faculties met with in hysteria receive lucid descriptions, and the part is illustrated by accounts of interesting cases; the multifiform character of the disease is nowhere better shown than in this relation. At the close of the chapter an endeavor is made to harmonize all the facts with physiological teachings. We fully sympathize with the trial; the result could only be tentative in the present state of knowledge. Hysterical Mania is the title of the next part. Here many clinical ob-

servations of cases of delirium, with hallucinations, of suicidal impulses, and transient erotic manifestations are recorded; the rarity of actual dementia is insisted upon; and the delirium of drunkards and hysterical delirium are compared with one another. The epidemic features of hysterical mania are also pointed out. The medico-legal aspect of hysteria is a subject with which Du Saulle is perfectly "at home." This section, which constitutes a third of the contents of the volume, is profusely illustrated with records of cases which for depth of interest and wealth of incident fully vie with the most realistic novels of French literature. The last chapters are devoted to questions relating to the nature, prognosis, and diagnosis of the disease; its treatment receives short but sufficient attention. In an appendix the author treats of nymphomania, which he regards as a different affection from hysteria, although the two may be combined in the same individual. Erotomania is separated from nymphomania; the former is a disease of the imagination not characterized by the excessive use of the physical organs.

St. Bartholomew's Hospital Reports. Vol. xviii.

1882. Edited by W. S. CHURCH, M.D., and JOHN LANGTON, F.R.C.S. London: Smith, Elder & Co. 1882.

THE demand made upon contributors to annual volumes like this does not apparently affect the quality of the work which they produce. There seems to be less striving after elaborate theses, and a fuller recognition of the fact that such volumes should be mainly limited to the records of facts of diseases observed within the hospitals. This primary intention has sometimes been lost sight of. Opportunity is given for the review of many matters of clinical and pathological interest by the light of present experience, and the six-and-twenty papers contained in this volume embrace a very wide range of such subjects. Dr. Gee contributes, in the terse and undogmatic manner so characteristic of all his writings, a few notes of cases of Fitful or Recurrent Vomiting in Children; and in conjunction with Dr. Abercrombie he has an interesting paper on a case of Lesion of the Sympathetic Nerve in the Neck. The patient was a child four years and a half old, whose illness began with right hemiplegia and partial right ptosis with myosis, and passed on, with wasting, to paraplegia, an elastic swelling appearing on the right side of the spine in the upper dorsal and lower cervical region. Besides the myosis, there was further evidence of sympathetic involvement in the fact that the temperature of the right ear was three degrees higher than that of the left. The diagnosis arrived at was vertebral caries with abscess involving the inferior cervical sympathetic ganglion, and accompanied by a subacute descending poliomyelitis. The condition proved to be a sarcomatous tumour seated deeply in the neck and upper thorax, and growing into the spinal canal through the foramina. The ganglion was not to be found, and the spinal cord showed some evidence of change in the cervical region and below. Mr. W. H. Jessop furnishes a paper on two cases of the remarkable condition of Hemiatrophia Facialis, illustrated by photographs; he reviews the hitherto recorded cases, and points out that the cases he describes support the conclusion arrived at by Romberg that the condition is a trophoneurosis. Dr. Wickham Legg shows, in a brief article on the History of Exophthalmic Goitre, that the claims of Basedow have been exaggerated, and that the credit of the earliest recognition of the disease rests with the Dublin school, as represented by

Graves, Marsh, and Stokes. Dr. Vincent Harris in a paper on Cardiac Murmurs analyzes the facts relating to cardiac auscultation, and formulates propositions, the truth of which may well be accepted, which mainly assert that murmurs are not always present in valvular disease, and that it is often not possible to diagnose by the stethoscope conditions of the circulation producing murmurs apart from valvular disease from actual valve lesion. A valuable contribution to the statistics of the laryngeal conditions in phthisis is supplied by Dr. Ormerod, who records in a tabular form the results of a systematic examination in 100 consecutive cases of phthisis. He found the larynx to be normal in 25 cases; in 17 changes limited to the vocal cords; in 8 some affection of the ventricular bands—anæmia of larynx; in 16 affection limited principally to the arytenoid mucous membrane; in 7 to the inter-arytenoid space; 11 involving all the back of the larynx; in 11 subacute laryngeal catarrh, and in 5 general tubercular infiltration. Dr. Dyce Duckworth has an essay demonstrating the special relationships between Diabetes and Arthritism, including under the latter term, which he has imported from French authors, "all the special morbid conditions commonly recognized as rheumatic or gouty, whether these be articular or not." Dr. D. A. King analyzes seventy-five cases of Typhoid Fever occurring in the Epidemic of 1882, in which he clearly shows the evil influence of delay in seeking admission to hospital—not only the mortality rising in proportion to the lateness of admission, but the severity of the complications. He also demonstrates that there is no relation between relapses and the taking of solid food, and concludes with some observations on constipation—a symptom of unusually frequent occurrence in the cases analyzed. A tabular statement is appended, and notes of a few selected cases. Dr. Steavenson contributes a paper on Tracheotomy, Dr. S. West one on Pain and Hemorrhage, and Dr. Moore one on cancer of the pancreas. Passing to the surgical papers, we may call attention to Mr. Walsham's very carefully compiled statistics respecting the operation of trephining, and the conclusion at which he arrives, that the operation is not *per se* a dangerous one. Mr. Howard Marsh gathers up his experience of the orthopaedic department in an interesting paper, in which he reviews particularly the condition of rickets, knock-knee, flat-foot, and lateral curvature, with reference to their treatment; Mr. Willett also contributing a paper on the Treatment of Flat-foot. Mr. Harrison Cripps writes upon Imperforate Rectum and Anus in Infants, distinguishing the varieties of this malformation, and describing the methods of operating most likely to be successful in their object. Mr. Langton has a paper on Hernia of the Ovary based upon his own experience, which has led him to think that it is a condition far more frequent than is usually supposed, but not often calling for surgical interference. Mr. Butlin supplies a record of the work done in the laryngeal department, dwelling especially on a few of the more interesting cases. Dr. Champneys writes upon the Scoliotic Pelvis in a paper that bristles with figures of the various measurements made in seven specimens he examined. Nor must mention be omitted of Dr. N. Moore's contribution on the Physicians and Surgeons of St. Bartholomew's Hospital before the Time of Harvey, a paper of much interest, in which he brings lucidly before us the manner in which they worked, and quotes largely from their writings, especially from those of William Clowes, who was surgeon from 1575 to 1585, and who appears to have been in many ways a notable man. The volume—which, it will be seen, is full of interesting

matter—concludes with reports of the meetings of the Abernethian Society, a list of specimens added to the museum, and the reports of the registrars for 1881.

Auscultation and Percussion. By SAMUEL JONES GEE, M.D. Third Edition. London: Smith, Elder & Co. 1883.—At the time when the first edition of this very useful and accurate little work appeared there were not nearly so many text-books of the kind in circulation; but it is not too much to say that although of late more than one excellent book on Physical Diagnosis has been issued, yet this of Dr. Gee's still maintains the pre-eminence it always held. Limited in scope, but dealing with the most important methods employed in clinical medicine, it is valuable on many accounts. There is a freshness and an originality about it which, combined with thoroughness and precision, convey the idea that the author has given here the results of his own careful observation, whilst endeavoring to enjoin the same care and accuracy on others. The clinical student cannot do better than take Dr. Gee as his guide, and he should endeavor to make himself master of the principles as well as of the practice so forcibly and clearly expressed by the author. The whole art of medicine, we were told, lies in observation; and we could well wish this maxim to be taken seriously by every hospital clinical clerk. The examination of the chest affords a great field for the exercise of his faculties, and he should omit no opportunity of making that examination as thorough, precise, and accurate as possible; every day that he enters the ward he will find scope for this practice, and the more he faithfully pursues it the deeper interest will it have for him, whilst from an educational point of view, in the training of eye, ear and hand, the gains derived from such study are not to be counted.

A Synoptical Guide to the Study of Obstetrics. By ROBERT BARNES, M.D. London: Smith, Elder & Co.—This little book is a sort of copious table of contents of the subjects embraced in midwifery. The materials are grouped under certain headings, and are full and well arranged. The work is intended to serve (1) as an index to a work on obstetrics about to be published by the author, in conjunction with his son and Professor Milnes Marshall; (2) as a syllabus for students attending lectures on midwifery; (3) as a guide to indicate to the student of obstetrics the subjects a knowledge of which he should possess; (4) as an aid to memory with view to examination.

Archives de Physiologie (BROWN-SÉQUARD, CHARCOT, VULPIAN), No. III., Mars, 1883.—This part contains the following memoirs:—1. Histological Research on the Poison Glands of the Toad, and on the Modifications in their Evolution resulting from Electric Stimulation of the Animal, by G. Calmels. 2. On the Nucleated Red Corpuscles of the Blood of the Adult, by G. Hayem. 3. Research on the Action of some Toxic and Remedial Agents on the Red Globules of the Blood, by M. Mayet. 4. On the Inoculation of Tubercle in the Ape, by MM. Dienlaffoy and Krishaber. 5. Experimental Researches on the Transmission of some Virulent Diseases, and a particular Charbon from the Mother to the Fœtus, by MM. J. Straus and Ch. Chamberland. 6. On Cylindroma, or Alveolar Epithelioma, with Myxomatous Invasion, by M. L. Malassez.

Epitome of Skin Disease. With Formulæ for Students and Practitioners. By the late TILBURY FOX, M.D., F.R.C.P., and T. COLCOTT FOX, M.B. Third Edition by T. COLCOTT FOX, M.B., Physi-

cian to the Skin Department of the North-west London Hospital. London: Henry Renshaw. 1883.—We are glad to see that a third edition of this useful little book has been called for. Dr. Colcott Fox has carefully revised the whole, and in places has, with advantage, amplified the text. This edition is certain to maintain the popularity enjoyed by the previous ones.

The Student's Guide to Surgical Diagnosis. By CHRISTOPHER HEATH, F.R.C.S., Holme Professor of Clinical Surgery in University College, London, and Surgeon to University College Hospital, etc. Second Edition. London: J. & A. Churchill.—The fact that a second edition of Mr. Heath's work has been so soon called for is sufficient evidence that the book is appreciated by the class for whom it is especially intended. There is no modification of the plan of the work, and the only alterations in this edition are amplifications in a few places and the addition of a very complete index.

Questions on Human Anatomy. By SAMUEL O. L. POTTER, A.M., M.D. Philadelphia. Test Series, No. I. London: Henry Kimpton. 1883.—This is a little book specially intended to help men in preparing for examinations in anatomy. It is more than its title implies; for it contains answers as well as questions. Indeed, it is a very condensed description of the bones, muscles, nerves, and lymphatics written in the form of answers to questions. It belongs to a class of books with which we have not much sympathy; but of the class it is a good specimen, being accurate and carefully done.

Medical Annotations.

"Ne quid nimis."

CO-EXISTENT DEFECTS OF URO-GENITARY ORGANS.

THE concurrence of two or more congenital curiosities tends to call forth a more considerable amount of conjecture and speculation than the mere presence of a single extraordinary defect. The wisdom of this tendency of the human mind may certainly be called in question, because we should have thought that one incident might, or perhaps ought to, excite as much attention as a number of odd occurrences. At all events, the co-existence of absence of one kidney with defects in the organs of generation is a sufficiently noteworthy phenomenon, and Dr. Guttman has recorded a male and female instance of this event in the April number of Virchow's *Archiv*. The first case was that of a boy aged fifteen years, who succumbed from Pott's disease of the spine. The right kidney and ureter were totally wanting, the left were much enlarged, and there was waxy degeneration of the glomeruli. The right vesicula seminalis was absent, as well as the right vas deferens; the corresponding tissues of the left side were of small size. Both testes were present and apparently natural, though, owing to a mistake, these were thrown away, and not properly examined after the autopsy. The second instance occurred in a female aged twenty, who died from phthisis. Again the right ureter and kidney were not present, the aorta was small, and there was no right renal artery. The external organs of generation were almost entirely undeveloped, the nymphæ and clitoris hardly recognizable, and the orifice of the vagina and that tube itself very narrow. A hymen was present. The small and long uterus were apparently kinked towards the right, at the junc-

tion of the body with the neck. The left broad ligament was normal, the right was inserted at the site of the kink, so that the whole right side of the body of the uterus lay free in the pelvic cavity. This circumstance and the apparent angularity of the uterus made it probable that a two-horned womb had to be dealt with, of which the right horn was scarcely at all developed. The right and left ovaries were small; the uterine half of the right Fallopian tube terminated in a blind extremity. There are now on record in literature about seventy instances of congenital absence of one kidney. Beumer collected altogether forty-eight; in twenty-two of these there was disease of the remaining kidney, enough to cause death; in twenty-six instances, on the contrary, the present kidney was healthy, although enlarged and heavier than normal. By careful micrometric investigations the enlargement was shown to be due not only to an increase in size of the glomeruli and urinary tubules, but also to a hyperplasia of the renal tissue.

THE BILIARY CAPILLARIES.

THE precise histological structure of the capillary network of bile-ducts in the lobules of the liver has not been satisfactorily settled. Is there a special epithelioid lining to these minute channels or not? M. Kanellis has communicated to the *Académie des Sciences* a note of some investigations made on the livers of rabbits with the aid of injections of nitrate of silver. The conclusion at which the histologist arrived was to the effect that there does exist a flat, thin, tessellated epithelial lining of the ultimate biliary canaliculi, and that the larger ducts possess a coat of prismatic cells. This observation is believed to afford grounds for a belief in the existence of a distinction between the biliary and glycogenic functions of the liver; the epithelium of the biliary channels presiding over the functions of bile secretion, whilst the hepatic cells proper are devoted to the formation of glycogen. When the small size of the intralobular biliary capillaries is borne in mind, the determination of the presence or absence of a special epithelial lining, even with the aid of injections of argentic nitrate, will certainly not seem to be an easy matter, especially when we remember that an inference in histology is seldom or never a matter of direct observation. The distance, too, between such cells of doubtful existence and the genuine hepatic tissue is so infinitesimal that the relegation of one function to one structure must be an act of discrimination of so delicate a nature that we do not think much weight ought to be attached to the suggestion offered.

PARASITES OF FISH.

AMONGST the objects of interest to the profession shown at the International Fisheries Exhibition are several small collections of entozoa and ectozoa infesting fish, oostacea, shellfish, and other aquatic animals. The special commissioner from the Gothenburg Museum, Dr. A. H. Malm, exhibits a few beautifully mounted parasites from marine fish and from two cetaceans. Professor Carmichael McIntosh, of St. Andrews, shows a series of interesting parasites from salmon captured in the Tay. They are very effectively displayed. So far as we have observed, the only "exhibit" exclusively devoted to parasites is the one sent by Dr. Cobbold. It comprises some eighty bottles, containing nearly as many distinct species. Some of the worms are of considerable rarity, and many have been transmitted from great distances. From the complete list given in *Land and Water*

we find that the exhibitor has taken much trouble to acknowledge his indebtedness to the various collectors. Thus there are three specimens which were obtained by the late Charles Darwin off Patagonia in 1835. Acknowledgments are also made to Dr. Günther, of the British Museum, to Surgeon-Major Francis Day, to Dr. John Anderson, of the Calcutta Museum, to Dr. Carmichael McIntosh, to Professor Coughtrey, of Otago, to Mr. Jardine Murray, of Brighton, to Dr. John Lowe, of Lynn, to Dr. Burge, of Shanghai, to Mr. Charles Tomes, to the late Drs. Pechey and Lauder Lindsay, and to Drs. Seccombe, Charles Davidson, and Henry Day; and, lastly, to the lamented Frank Buckland, whose enthusiasm would have been stirred to the highest pitch had he survived to take part in the International undertaking. We may add, what perhaps is not very generally known, that tapeworms and other entozoa, as well as certain ectozoa, are amongst the ascertained causes of diseases that prove fatal to fish and other aquatic animals.

SEVERE HÆMORRHAGE AFTER TOOTH-EXTRACTION TREATED BY TRANSFUSION.

THE *Revue Odontologique* for April contains an interesting account of a case of almost fatal hæmorrhage after tooth-extraction. The patient, a young soldier of twenty-two, with a marked history of hereditary and collateral hæmorrhagic diathesis, was admitted to the *Hôtel Dieu*, and had some molar roots removed without telling the house-surgeon any facts as to his history, and the operation which was performed was followed by profuse hæmorrhage of a dark color, without clots. Next morning plugging with lint and perchloride of iron was tried without permanent effect. On the third day actual cautery was tried at the bottom of the socket, followed by plugging with compressed sponge, the jaws being fixed by a bandage, and ergotine subcutaneously injected. On the fourth and fifth there was no hæmorrhage; injections continued. Next day (the sixth) the bandages, etc., were removed, owing to sloughing and suppuration of the gums, and from the raw surfaces profuse bleeding recurred, and no local measures were effective to arrest it. On the eleventh day the patient was moribund, and it was decided to try transfusion of blood. After plugging the socket again, 100 grammes of blood were transfused into the cephalic vein, with immediate relief to the patient. In three hours the trouble began again and continued until next morning, when, after a second transfusion, the patient began to revive, although an access of syncope nearly proved fatal during the operation. However, the hæmorrhage was stopped, and in six weeks the patient was discharged cured.

THE INDIGO TEST FOR SUGAR.

At a recent meeting of the Clinical Society Dr. Oliver showed how the well-known property of indigo carmine being converted into indigo white in the presence of certain organic matters might be rendered available for testing for sugar in urine, by means of specially prepared test-paper. The indigo test for sugar in urine has been before the profession for some years, having been originally suggested by Mulder. In the Sydenham Society's translation of Neubauer and Vogel the test is fully described. The reaction has also been long in use in operations connected with dyeing calicoes. It is based on the fact that indigotine, the coloring matter extracted from commercial indigo, with certain oxidizable organic matters, such as glucose, gallic acid, pectic acid, etc., in the presence of al-

kalies possesses the property of fixing hydrogen and of being converted into colorless indigo, but which is susceptible of reconversion under the influence of oxygen into indigotine. The change from indigotine into indigo white may be represented by the following equation:—Indigotine 2 ($C_{16}H_7NO$) + $H_2 = C_{16}H_9N_2O_2$, or indigo white. Many other organic as well as inorganic substances besides sugar seem to possess the property of decolorizing indigo in alkaline solutions—in fact, the processes used in the different factories are extremely various. Even the processes of alkaline fermentation and butyric acid fermentation will produce the change. We do not make these remarks with a view to disparage the test, and Dr. Oliver is deserving the highest credit for his endeavor to make it readily available for clinical purposes, but to suggest a caution as to the deductions drawn from results obtained by it. It is more than probable that a test so favorably introduced by Mulder and Neubauer must have been found on more intimate acquaintance defective in its practical working, or it would not have fallen into comparative disuse. We believe, however, that while it cannot supplant the copper test, it will prove a valuable supplement. The copper test, as is well known, is not reduced by all forms of sugar, whilst the indigo reaction is given by every form of carbohydrate. It may thus be made available for distinguishing between those forms of sugar sometimes present in urine which give no reaction with copper, and may so help to distinguish these cases from true glycosuria.

A CASE OF POISONING BY CARBOLIC ACID.

A CASE has recently occurred at Calcutta which presents many points of medical interest. A practitioner of that city was charged with causing the death of his cousin, a boy of five, by administering an overdose of carbohc acid in the form of an enema. From the evidence it appears that the deceased had been suffering from diarrhoea for some days, but had not been very ill, and had been able to play about much as usual. There had been a little blood in the motions, and worms were suspected. On the afternoon of Nov. 26th the accused was called in to see the patient. The little boy was at the time in the garden, and on being sent for came running up and exclaimed, "Oh! papa has brought me a new doctor!" He was taken to his bedroom, where he was undressed and carefully examined. The doctor gave it as his opinion that there was no enlargement of the liver or spleen, but thought that the symptoms were due to worms. He asked for a bottle of carbohc acid and an enema apparatus. He then measured out an ounce of the acid; but on the father protesting that it was too much, he said, "Oh! very well; I will mix it with forty parts of water, and only inject half." On the father again protesting and saying, "Don't you think it will be too strong?" the doctor assented, and about a pint more water was added. The child was then placed on its back, and the injection commenced. After about half the fluid had been introduced, the apparatus was withdrawn, the rectum, however, being supported so that nothing should escape. The child complained of no pain, but a few minutes later was found to be insensible. The friends, in answer to their inquiries, were informed that it was only shock, and was of no consequence. An attempt to give brandy by the mouth was unsuccessful. Other medical men were then called in by the father, and artificial respiration was resorted to, but the child never recovered consciousness, and died the following morning at half past seven. No post-mortem examination was

made, but it was stated that the body smelt strongly of carbohc acid. The exact quantity injected was not known, but the prisoner volunteered the statement that he used a 1 in 60 solution, and injected about 18 ounces, representing 144 grains. For the defence it was urged that it had not been conclusively shown that the fluid injected was carbohc acid. It had been obtained from a native dispensary for doctoring horses, and it might have been carbohc acid or something much stronger. Then it was urged that it was not clear that the child had died from carbohc acid poisoning at all. The parents had refused a post-mortem examination. It might have died of ulceration of the bowel or any other disease. And again, even supposing that the child had died of carbohc acid poisoning, it did not prove that an overdose had been given. What was there to show that the child was not unusually susceptible to the action of carbohc acid, that it was not, in fact, a case of idiosyncrasy? The prisoner had studied medicine at Edinburgh and Glasgow, and at the Rotunda at Dublin, and was it to be supposed that he did not know more about the action of the drug than other gentlemen who had not had these unusual advantages? The jury ultimately found the prisoner guilty, but recommended him to mercy. The judge, in discharging him with a caution, remarked that perhaps it would be as well to give rather smaller doses in future. The accused is certainly to be congratulated on the result of the trial, but we fear that he owed his acquittal rather to the ingenuity of his counsel than to his knowledge of materia medica or therapeutics. It may interest him to note that Taylor, Murrell, Woodman and Tidy, and others consider that the fatal dose of carbohc acid is a drachm, and that recovery even in adults is very exceptional after half an ounce. At the same time it is only fair to mention that Reichert in his "Contributions to the Study of the Toxicology of the Cardiac Depressants," mentions the case of a woman, aged twenty, who recovered after the injection of 145 grains of carbohc acid for the cure of worms.

BATHING.

ALL are agreed that bathing is a healthful practice: first, because it is cleanly; and second, because it is a precautionary measure against risk to life by drowning. We are fully prepared to endorse the proposition that boys should be allowed to bathe as often and as freely as may be practicable. It is, however, necessary to raise a protest against the recklessness which too commonly attends the recourse to bathing as an exceptional, or at most seasonable, exercise, by those who are, though eager perhaps, not always physically fit to bathe. There is, practically, less danger in bathing all the year round than in doing so only at certain periods. When to begin bathing? In what weather to bathe? and under what condition of the bodily state to bathe? are questions of considerable perplexity, and by no means always easy to answer. The general rules which should guide the judgment are, doubtless, in the main physiological—that is to say, they relate chiefly to the functions of life and their healthy performance: Obviously it is not right to dare the dangers of a "chill" either when undressing or by immersion in the cold water. Speaking generally, the "reaction," on which everything depends, will take place in proportion to the healthy circulation of the blood and the natural heat of the body when the bath is taken. If there be much moisture on the surface, it is difficult to tell what the actual temperature of the organism really is. In most cases a sweating surface indicates some

measure of exhaustion already set in. In any case it is unwise to bathe when copious perspiration has continued for some hour or more, unless the heat of the weather be excessive or the sweating has been induced by loading with clothes rather than by exertion. When much perspiration has been produced by muscular exercise, it is unsafe to bathe, because the body is so fatigued or exhausted that the reaction—that is, the return of the momentarily displaced blood to the surface—cannot be ensured, and the effect may be to congest the internal organs and notably the nerve centres. It is from congestion of the nervous centres we get cramp, so often fatal in bathing. The fact of the “reaction” does not, of course, constitute the whole phenomena of bathing; but it is so important and comprehensive that we may take this as the point on which everything turns. Conditions under which a vigorous return of blood to the surface cannot be confidently counted upon are not favorable to bathing. If, therefore, the weather be “chilly” or there be a cold wind so that the body may be rapidly cooled at the surface while undressing, it is not safe to bathe. Under such conditions the further chill of immersion in cold water will take place at the precise moment when the reaction consequent upon the chill of exposure by undressing ought to occur, and this second chill will not only delay or altogether prevent the reaction, but convert the bath from a mere stimulant to a depressant, ending in the abstraction of a large amount of animal heat and congestion of the internal organs and nerve centres. The actual temperature of the water does not affect the question so much as its relative temperature as compared with that of the surrounding air. Practically, there ought to be a good deal of difference between the two, the water being much lower than the air and the body being—without great or long persisting perspiration—much warmer than the water, of course, but not so much warmer than the atmosphere as to be chilled by undressing. In short, the aim must be to avoid *two* chills; first, from the air, and second, from the water, and to make sure that the body is in such a condition as to secure a quick reaction on emerging from the water, without relying too much on the possible effect of friction by rubbing. Thinking these brief hints out it will be obvious that both weather and wind must be carefully considered before bathing is commenced, and that the state of the organism as regards fatigue and the force of the circulation should also be considered, not merely as regards the general habit, but the special condition when a bath is to be taken. These precautions are eminently needful in the case of the young or weakly.

CIGARETTE SMOKING AGAIN.

SOME months ago we took occasion to offer a few remarks on the practice of cigarette smoking. It was not with any desire to indulge in a tirade against tobacco and what is called “nicotine poisoning” we then discussed the subject in these columns. Our observations were misunderstood in some, misrepresented in other, and sharply criticised in many, quarters. It is urged in rejoinder to our allegations that medical men not unfrequently themselves smoke, and, like other smokers, use cigarettes. Our warning was against the too habitual, and daily increasing, practice of keeping cigarettes in the mouth almost continuously. If cigarettes were smoked by the young men of England as they are by most foreigners no harm would probably result. In other countries the little roll of tobacco is held loosely between the fingers and applied daintily to the lips, a mere puff

of the smoke being inhaled and as quickly blown away. The prosaic Englishman places his cigarette firmly between his lips and leaves it there, sucking in and retaining the smoke, thereby poisoning the saliva, and, which is worse, giving the smoke time to deposit its oily particles in the lining membranes of the mouth, the throat, and the air passages generally. It is directly demonstrable by experiments that tobacco smoke will throw down nicotine with extraordinary rapidity, and the proportion deposited by the smoke of finely cut leaves burnt quickly, as the tobacco in a cigarette is burnt, is greater than that thrown down by the smoke of a cigar or pipe. In cigarette smoking the tobacco leaf is reduced to very fine shreds, and it is consumed with great celerity. The smoke passes directly into the mouth, unless a mouth-piece is used, and whatever nicotine there may be to affect the organism of the smoker is taken up with especial avidity. As regards the influence of cigarette smoking on the pulse, this is in many cases, undoubtedly, strongly marked. The sphygmograph gives tracings which are characteristic of the depression produced by tobacco on the vasomotor centre and nerves—that is to say, the apparatus by which the calibre of the smaller blood-vessels is regulated, and the pulsating current of the blood normally converted into a continuous flow of the nourishing fluid—and these tracings are more characteristic in the case of the habitual smoker of cigarettes than in that of the smoker of cigars or a pipe. This fact has fallen repeatedly under observation. Another feature of the case against cigarette smoking is the relatively greater dryness of the mouth and throat, and therefore desire for a “brandy-and-soda” or some other stimulating beverage which attends the smoking of cigarettes, than that which is caused by other modes of indulgence in tobacco. We neither share the fashionable belief that alcoholic drinks are injurious when taken in strict moderation, nor do we for a moment think a moderate use of tobacco is to be deprecated, except in special cases; on the contrary, we are convinced that for the relief of many mind and nerve troubles, and for the reduction of needless and mischievous excitement in the brain and other nerve centres, tobacco smoking is often useful; but, at the same time, we are persuaded that a protest against the habitual smoking of cigarettes is needed, and we think it timely to repeat this protest in warm summer weather; for it is undoubtedly when the atmosphere is heated and the pulse is liable to be quickened by the slightest nervous excitement or muscular exercise, those who smoke find the genial influence of small doses of tobacco both soothing and recuperative.

INCUBATION OF DISEASED EGGS.

SOME observations in a field of experimental investigation hitherto but little, if at all, the subject of special research, were contributed by M. Barthélemy before a recent meeting of the Académie des Sciences. The conclusions at which M. Barthélemy arrives are remarkable, and may turn out to be of much value in throwing light on kindred questions. In a farmyard which had been during the past year the site of an epidemic of fowl-cholera, a fowl presented this year, towards the end of February, all the symptoms of the affection, and after a protracted illness died. Fourteen eggs were laid by this bird during its illness, and these were subjected to incubation side by side with some eggs obtained from a normal fowl. Closely watched, the two kinds of eggs presented no recognizable difference so long as the circulation lasted in the yolk of the egg. Notable differences were, however, detected when the respira-

tory function was transferred to the allantois; this would be at about the ninth day of incubation. The added eggs—if that term may be used—ceased to develop; not one was hatched. Examination of the eggs, opened with the usual precautions, showed that beneath the shell, and at the surface of the allantois, an extravasation of black blood existed, which was characterized by the presence of an odor quite similar to that arising from fowls dead of cholera. Pending the examination the umbilical artery continued to pulsate slowly, a fact which goes to show the tenacity of life of these embryos. The embryo proper was seen, so to speak, swamped in the bottom of the amniotic sac, which was swollen with a large quantity of fluid, whilst all trace of albumen had disappeared. The blood of the diseased egg was full of bacteria, and the amniotic fluid contained monads of very minute size. M. Barthélemy contends strongly for the notion, that the ovum contained the germs of the microbes with which the parent's blood teemed, and that these germs only developed when, by the formation of the allantoic circulation, an aerial respiration imparted to the circulating blood the necessary amount of oxygen; it is of further interest to remark that just at this time the embryo begins to assume the special features of a bird. Two out of three fowls succumbed after inoculation with the débris of the diseased embryo. Lastly, it ought to be mentioned that cholera was still rife in the farm, and that other fowls were affected.

A NEW TREATMENT FOR GLAUCOMA.

FROM a review of the thesis in *L'Union Médicale* we learn that M. Trousseau, *ancien interne des hôpitaux*, has arrived at certain conclusions with regard to the value of what is believed to be a new method of treating glaucoma. The method consists in stretching the external nasal nerve. The details are not mentioned, but it would appear to be a measure of very simple sort, and of innocent application. It is believed that it may succeed when iridectomy and sclerotomy have failed. The prodromal stage is not too early for its application, and the necessity of having recourse to the gravest measures may be prevented. Other sensory nerves of the orbit ought to be tried if elongation of the external nasal fail. The above conclusions were drawn from the results of ten observations. Allowing the truth of the assertions, the explanation would be of as doubtful a nature as the *rationale* of the nerve-stretching in locomotor ataxy. We may truly say, *Ignotum per Ignotius*.

FALSE TEETH.

AN inquest was held at St. Bartholomew's Hospital recently by Mr. Langham on the body of a man from Rhayader, in North Wales, who died from the effects of swallowing a small plate carrying two artificial teeth. He was brought from Wales to London, and admitted into the hospital, and an operation was performed to relieve the urgent dyspnoea, but death eventually supervened owing to an abscess caused by the impaction of the plate. There is no rose without a thorn, no advantage without a drawback. Even the blessing of false teeth to the toothless has a possible curse hidden beneath its fair exterior: the teeth may break loose from their fixings or fastenings either when in use or while the wearer sleeps, and being either swallowed or drawn with the breath into the larynx, trachea, or bronchus, become converted from an aid to living into a cause of death. The moral of this consideration ought to be not that the dread of being "in peril by false teeth" should

frighten persons from wearing them, but that dentists should be particularly careful to provide secure fastenings. There can be no doubt that there is a great deal of careless work in the fitting of artificial teeth. Setting aside the multitude of clumsy and inartistic teeth thrust into the mouths of the ignorant or too forbearing, there is a large proportion of cases in which safety is sacrificed to seeming comfort or appearance. It may be easy to wear a set of teeth, or to keep a single tooth in place with ordinary attention when the attachments have been reduced to a minimum, but a very little careless eating or talking may, at any moment, render such attachments of no value. We have heard dentists themselves express wonder at the fact that "sets" supplied at the special request of their wearers, with little or nothing to hold them in place, could be worn. Dentists should insist on making the teeth they apply thoroughly secure; and their clients should submit the question of fastenings, both as regards number and extent, entirely to their judgment.

DEATH FROM EMOTION.

THE *Philadelphia Medical Times* records a very instructive case in which a man died from fright, and where the death narrowly escaped being attributed to ether. The patient had received a severe injury to his hip during some blasting operations. Some days after the injury a consultation was held on his case in the Wilkesbarre Hospital, and it was considered necessary to administer ether. The man objected to this and urged that his heart was weak, but it was considered necessary to anaesthetize him. This decision seemed to affect the man strongly, he breathed with great difficulty, asked for the windows to be opened, and in a few moments died. No ether or other anaesthetic had been administered, and he had not suffered any pain from the partial examination of the hip that had been made. No particulars of the actual state of the heart are given, but we are told a "murmur" was present. There is little difficulty, however, in tracing the death to a powerful inhibitory influence upon a weak heart. The case has many parallels, and a very good one is quoted by the *Philadelphia Times* of a boy in India who, mistaking in the night a harmless lizard creeping over his leg for a bite from a cobra, immediately became collapsed and died in spite of all attempts to restore him. Had the surgeons in the first case begun to administer ether, this death would have been wrongfully attributed to the effects of the anaesthetic.

Correspondence.

"Audi alteram partem."

SIR HENRY THOMPSON ON CIGARETTE SMOKING.

To the Editor of THE LANCET.

SIR—I think I might, if permitted, offer you a practical hint of some value in connection with cigarette smoking, which I think is not altogether appreciated by the author of your notes on the subject.

First, the cigarette, without a mouthpiece, is really never smoked more than half way through in the East, where cigarettes are very cheap. It is well understood there, as it is by all practiced cigarette smokers, that every inhalation from a

cigarette slightly deteriorates in quality from the first. A small deposit of the very offensive oil of tobacco is deposited in the finely cut leaf, which acts as a strainer, and intercepts the deposit as it passes. Very little of this arrives in the smoker's mouth if he stops when half is consumed. I have seen many oriental smokers who consume no more than a third. Turkish ladies, for example, as I have had personal opportunity of observing at Constantinople, will smoke fifty or upwards in a day, but, I need scarcely say, only in the manner I have described.

Secondly, if a cigarette with a card mouthpiece is employed, the noxious matter may be intercepted by always introducing a light plug of cotton wool into the tube. If now the cigarette is nearly consumed, a considerable quantity of brown and very offensive matter will be found in the cotton wool, from the evil of which the smoker is thus preserved.

Thirdly. Some years ago I designed a cigarette-holder or mouthpiece, which opened transversely in the middle, disclosing a small cavity, which is filled with cotton wool. It would surprise many people, perhaps, to find that the result of smoking six cigarettes only in this tube is that this plug is saturated with a brown fluid like treacle, of powerfully offensive odor, and disagreeable almost beyond belief. The wool then requires to be changed, and in this manner the evil of smoking is very greatly diminished. Several of these were constructed by a well-known tobacconist close to your office in the Strand.

Lastly. The maximum of pernicious influence which occurs through cigarette smoking is attained by the practice of inhaling the smoke largely direct into the lungs, where it comes into immediate contact with the circulation, and the toxic effect is so strongly perceptible after three or four consecutive inhalations, and so felt by a sensitive person to the very tips of the fingers. I have no doubt that the effect would in most cases be notably recorded by the sphygmograph. Such smoking is of course, or ought to be, exceptional. All the fragrance, with a little only of the toxic effect, is obtained by admission of the smoke into the mouth only, still more by passing it through the passages of the pharynx and nose; but it is the pulmonary inhalation referred to, often associated with cigarette smoking, and rarely with the pipe, which constitutes the chief mischief of the cigarette. I may say, in passing, that that well-known oriental method of smoking, practiced by means of the narghileh, in which the smoke, although drawn through water, passes invariably through the lungs, explains the powerful effects which sometimes unpleasantly surprise novices in its use.

Smoked, then, simply, and with cotton wool interposed, I do not hesitate to regard the cigarette as the least potent, and therefore the least injurious form of tobacco smoking. Without this precaution it may be made, although not necessarily, the most ready means of conveying the active principle of tobacco, by means of smoke, into the system.

I am, Sir, yours truly,

H. THOMPSON.

Wimpole-street, W., May 28th, 1883.

To the Editor of THE LANCET.

SIR—With reference to the article on this subject, I should like, if you would allow me, to make a few remarks.

In your article you infer that smoking cigarettes in the foreign way does less harm than the English mode, because in the latter case the smoke is

retained longer in the mouth. Now, I have lived for several years abroad, and I know that the French, Italians, Spaniards, Germans, and I have heard also that the Russians, "inhale" the smoke from the cigarette—that is, they swallow it, so that the smoker after drawing down a whiff of smoke, can, if he chooses, speak, or even drink a glass of beer, and after that bring the smoke up again and eject it. This is their usual way of smoking cigarettes, but in London ten years ago, as far as I could see, "inhaling" was not much known, but I notice that the numbers here who now adopt it are increasing every year, and they, after having acquired the habit, will tell you that this is the only way they care to smoke a cigarette. But if the mere retention in the mouth of the smoke is so bad, how much more must it be so in the case of the foreigner who always "inhales" or swallows the smoke; and yet it is held in your article that the foreign way of smoking is the least injurious.

I do not know whether the attention of the medical profession has been drawn to the subject of "inhaling," but if it has, I and many other "outsiders" with whom I have conversed on the subject would be glad to know their opinion, whether inhaling is much more injurious than ordinary smoking, and what are its effects; and I think that it would be very useful to the public to have their views, as the practice of inhaling seems to be spreading rapidly.

I am, Sir, your obedient servant,

C. E. D.

May 29th, 1883.

TETANUS OR HYDROPHOBIA.

To the Editor of THE LANCET.

SIR—I beg to send you the following case, which you may deem worthy of insertion in THE LANCET:—

A female Hindoo child, aged seven years, was bitten on March 30th, 1883, by a dog supposed to be rabid. The wounds, which were described as slight, were on the top of the head and top of the right shoulder, were cauterized as soon after the injury as possible with nitrate of silver, and both healed kindly within a week. About six weeks after the injury, or on May 14th, the child complained to the father that it experienced a sensation as if there were a worm in its ear, and afterwards complained of headache. Next morning the father states "she began to grind her teeth, and I then brought her to hospital." The case was admitted into the regimental hospital on the morning of May 15th, and, from the history, it was diagnosed to be one of hydrophobia. The following symptoms were noted:—Frequent fits of crying as if afraid of something, and paroxysms of cramp over the whole body. Trismus was marked, the grinding of the teeth being caused by spasm of the muscles of mastication. The child had no dread of water, but had great difficulty in swallowing fluids, which it did by gulps. There was no frothing at the mouth or dripping of saliva from the mouth at this period, although this is said to have happened immediately before death. During the whole day the child lay on its belly, and suffered from paroxysms of cramp, occurring at varying intervals, but always excited by being in any way disturbed. The same condition prevailed during the night. The temperature in the axilla was noted to be 99°. On the morning of the 16th I again saw the patient. It now suffered from very frequent attacks of cramp over the whole body, opisthotonos being marked. It had no dread of water, but refused to drink any. The pulse was

now weak and rapid, the temperature 99° 2'. The face had a wild expression, but there was no mental aberration. The jaws were firmly closed. At 1.45 it had a violent seizure of spasms, and died in the convulsions. The bowels were constipated throughout. Several other persons were bitten by the same dog, but to the present date this is the only one with serious results.

I am, Sir, your obedient servant,
J. E. FERGUSON, Surgeon, 9th Bombay N.I.
Poona, India, May 23rd, 1883.

A CASE OF SCURVY OCCURRING AS A COMPLICATION OF HEART DISEASE AND SYPHILIS.

To the Editor of THE LANCET.

SIR—The following case is, I believe, of sufficient interest for publication.

G. M—, aged forty-five, came under my care for the first time in September last, suffering from long-standing aortic obstruction and regurgitation together with the usual train of symptoms denoting cardiac failure. He was also the subject of tertiary syphilis, having a large ulcer over the manubrium sterni connected with that bone, and symmetrical gummata in the sterno-mastoid muscles, which subsequently suppurated; he had, moreover, lost an eye from "inflammation" some years previously. The progress of the case presented nothing unusual till March this year; and, although distressful symptoms were markedly relieved by treatment, the condition of the patient was one of increasing weakness.

On March 19th he complained of unusually severe pains in his joints and back, and the following day petechiæ began to appear on the trunk and limbs. On the 21st a large brawny swelling appeared in front of the left elbow-joint, with deep-seated oedema of the forearm and hand. Subsequently effusion took place into the cellular tissue of each orbit, quite closing the eyelids; and the right forearm also was the seat of extensive intermuscular effusion. The petechiæ meanwhile increased in size and number. The gums, though unhealthy, were not particularly affected, but the fetor of the breath was almost unbearable. Intestinal hæmorrhage and bilious vomiting soon supervened, and the patient died on the 29th of March. The diet of this patient had not been at all limited in kind, and for a man in his condition he had, up to a fortnight before his death, taken a fair amount of nourishment; so that, although one cannot exclude mal-assimilation as a factor, I am inclined to attribute the origin of scurvy in this instance to the mal-nutrition resulting from disease. The combination of morbid elements present was peculiarly favorable to the production of profound cachexia—viz., a diseased and failing heart, impure blood, and an arterial system seriously affected, in all probability by the syphilitic poison.

I am, Sir, your obediently,
JAMES TURTON, M.R.C.S.
Heckmondwike, June 1st, 1883.

AN UNUSUAL PARTURITION.

To the Editor of THE LANCET.

SIR—In May, Mrs. D—, aged twenty-eight, a fine, well-made, fair woman, the mother of two children born at full period and who had had one miscarriage, was taken in labour after a pregnancy of six months and a half. Anomalous pains commenced about four hours previous to the birth of the child.

When I arrived the nurse told me the child was

just expelled, lying under the bedclothes between the mother's legs. Upon raising the sheets I found the whole contents of the late gravid uterus had been ejected. The placenta, membranes, waters, and the child were all intact; the mass was about the size of a large bat. The child was floundering about in the fluid, and struggling to be released. I raised the mass up by taking hold of the placenta, and found its total weight about nine pounds. The membranes were exceedingly tough, and to release the child I had to cut them with a pair of scissors, as I could not tear them open with my fingers.

This is the only case I ever saw born in this fashion, where the child was viable, out of 7,000 cases I have attended, the nearest approach to it being one other case where the child was four months old in utero, the preparation of which I have in spirits. It is remarkable that the child was alive in *membrana* after being expelled in this way, and it lived for some days after. The wonder is that there was not considerable hæmorrhage or inversion of the uterus. The mother stated the pains were not like that of labour, but a sudden "rush out of the contents of the bowels." She had a good getting up. Had I been present at the birth I should have ruptured the membranes, and thus prevented this singular and, as far as I know, unique labour, which may be classed as of the rarest kind.

I am, Sir, yours, etc.,
W. H. BORHAM.

Notting-hill, June 4th, 1883.

THE COLOR OF MILITARY UNIFORMS.

To the Editor of THE LANCET.

SIR—Relative to the proposed change of color in the uniform of our military, it may not be amiss to call attention to the following fact:—

When a ray of light passes through an ordinary convex lens, it is usually split up into its component colors, causing a slightly blurred colored border around the object. This is caused by the unequal amount of refraction to which the different colors are subjected. It (the splitting up of the colors) is prevented in the human eye by the unequal refractive power of the media, situate in front of the retina; the remedy existing however only while the image can be received exactly at its focal distance by the aid of the accommodating apparatus of the eye, causing by its failure the blurred trail or outline which surrounds the scarlet coat at a distance (?).

In the "spectrum" the red is the least refractive of all the colors, for which reason the eye has to bring its strongest accommodating power into action, and *ergo* focuses the red object as if it were considerably nearer than it really is. This of course would not be so apparent if the scenery around were of the same color or nearly so, but assuming the atmosphere colorless, the red stands out in bold relief.

Thus in our soldiers' scarlet tunic we seem to have considered the advantage we can give the enemy in choosing the least refractive of colors.

I am, Sir, yours truly,
OCULUS.

June 16th, 1883.

"APOMORPHIA."

To the Editor of THE LANCET.

SIR—about a year ago I was called to a stout, healthy woman who had swallowed an unknown quantity of morphine with suicidal intent. She was already unconscious, pupils contracted, and stertor-

ous breathing. As I could get her to swallow nothing, I injected into the arm, as soon as I could get it from a drug store about one square away, about one-eighth of a grain of apomorphia dissolved in water, which was followed in a few moments by copious vomiting. As the patient seemed to get no worse, nothing more was done, and she recovered in a few hours.

I have also used hypodermic injections of apomorphia in three cases of general clonic convulsions of children, all under four years of age. The convulsions in one were caused by commencing meningitis, in one by pneumonia, and in the third by intermittent fever. All recovered fully from the convulsions, but the one with meningitis died in about three weeks from the meningitis; the one with pneumonia lived one week, and died from the disease; and the other recovered in about two months, after a severe seizure of malarial fever, with possibly some meningitis, but is to-day almost an idiot, more than a year after recovery. All recovered perfect consciousness for about one week, showing that the apomorphia had nothing to do with death in two cases or with the idiocy of the third. I am, Sir, very truly yours,

F. JACKMAN, M.D.

S. Illinois-street, Indianapolis, Indiana, U.S., May 15th, 1883.

PRESENCE OF BACILLUS TUBERCULOSIS IN AN ABSCESS NEAR THE ANUS.

To the Editor of THE LANCET.

SIR—Six months ago a young clerk, aged twenty-one, came under treatment for hæmoptysis and other signs of phthisis; after about three months' treatment he got strong enough to return to his employment, at which he continued up to the commencement of this month. I saw him on the 5th, when he was suffering acutely from an abscess in the neighborhood of the anus, and, fearing, lest it might burst into the bowel and give rise to a painful blind internal fistula, I opened the abscess at once and let out a quantity of thin curdy fetid pus. A microscopic examination of this fluid by a half-inch object glass, after the usual process of staining, revealed the presence of great quantities of well-marked typical tubercle bacillus. Now, the presence of these organisms in this situation is interesting, as they tend to throw some light on the well-known connection between fistula and phthisis. On this account you may, perhaps, deem this note not unworthy of being recorded.

I am Sir, yours obediently,

R. C. SMITH, M.D., D.Sc.

Manchester, June 10th, 1883.

News Items, Medical Facts, &c.

THE battle of the codes in the United States rages as hotly as ever. Dr. J. W. Howe has resigned the Professorship of Clinical Surgery in Bellevue Hospital Medical College because he has understood that unless he could join with the rest of the faculty in supporting the code of the American Medical Association his resignation would be acceptable.

ARE FALSE TEETH NECESSARIES?—An interesting case bearing on the above question was recently decided before the Austrian district tribunal at Brünn. A dentist sued a gentleman of position for the cost of furnishing several false teeth to his recently deceased wife. The widower contended that the claim did not come within the scope of the befitting support which his wife was legally

entitled to receive, and argued that, although medical services would be covered by legislative enactment, such was not the case with the offices of a dentist. The court, however, decided against him, on the grounds that mastication must be defective with a deficient number of teeth, and thus their replacement is a matter of necessity to the bodily health.

PHOTOGRAPHY FOR PHYSICIANS.—The general idea associated with the practice of photography is one of dirt and "mussiness." This was eminently characteristic of the art a few years ago, but since the introduction of what is known as the dry-plate system, this has been entirely changed and the making of a photograph does not involve half the labor and dirt that is required in preparing and mounting ordinary specimens either for the microscope or the shelf. Physicians and surgeons can hardly fail to find the new system a great aid, both as an aid in consultation with their brethren at a distance, and as a means of recording peculiar cases. The Scoville Manufacturing Company manufacture special outfits for this purpose, and they publish a small book on the subject, giving full directions for the taking of photographs. This book will be sent free to any one who will send for it.

MR. SMEE'S GARDEN.—The *Gardener's Magazine* contains a brief description of the garden of the late Mr. Alfred Smee, situated at Wallington. It has now passed into the possession of Mr. H. Smee, who has religiously preserved it as regards its peculiar features and the idea it represents. It has of course been slightly modified by its present possessor, but for all scientific and artistic purposes it remains intact, a suitable memorial of a good and gifted man, a rural microcosm, in which may be seen very much of the material of which this world is made, and more particularly of its vegetable clothing. The idea of the late Mr. Smee was to encourage as many forms of vegetation as can be accommodated within the space of a few acres, and as far as possible to leave nature free. The garden has been many times described, but the best description, and, indeed, the only one worth mention now, was that given by Mr. Smee himself in a remarkable book, entitled "My Garden," published by Bell & Daldy in 1872.

PURE WATER.—It is probable that impure water is the cause of quite as much sickness as any other agent, and it is unfortunately the case that ordinary mechanical filters fail to remove some of the most deleterious ingredients. The great natural filters, those by which our springs and clear streams are purified, are beds of clay and soil; but this material is too cumbrous and bulky to be used for ordinary artificial filters. But the extraordinary powers of discoloring and defecating possessed by charcoal, and especially by animal charcoal, place within our reach a means of purifying drinking water which leave nothing to be desired. We have frequently passed filthy and offensive water through this material, and obtained a clear, limpid, and entirely sweet product. Of course the efficiency and convenience of a charcoal filter depends much upon the mechanical arrangements involved in its construction. An exceedingly simple and convenient filter, constructed upon this principle is that manufactured by the Stoddard Lock Company, of this city. It is cheap and may be readily applied to any water cooler or faucet. Descriptive circulars may be obtained from the company.

A Sketch

OF

THE ORIGIN AND DEVELOPMENT OF THE SCIENCE OF HYGIENE.

*Being the Inaugural Lecture of the Parkes Museum,
delivered on June 1st, 1883,*

By F. S. B. F. DE CHAUMONT, M.D., F.R.S.,

Professor of Hygiene in the Army Medical School, Netley.

To trace the history of the search of the human race after health would be almost tantamount to writing the history of the race itself. Fortunately, both for myself and my hearers, such an undertaking is neither expected nor intended. An inquiry into early wanderings and gropings after health would be doubtfully useful, even if it were likely to be interesting, for it would bear to the hygiene of the present day something of the same relation that the visions of the astrologer bear to the astronomy of Newton. Perhaps some might object that this is claiming too much for our subject, and that even its title to be treated as a science may be questioned. But much the same objection might be made to medicine, and perhaps even to other branches of knowledge which are conventionally included in the list of exact sciences. A careful examination, however, of the position which hygiene now holds will, I think, justify us in claiming that it has made such advances as may fairly entitle it to take its place among the progressive if not absolutely exact sciences. Its literature has been said with truth to be amongst the oldest in the world, the earliest records being religious ceremonial formulas which ever involved rules directed to maintain the health and efficiency of the people.

It has been proposed to place upon these walls the names of the illustrious dead who were the pioneers and founders of our science, and the difficulty will probably lie more in the wealth than in the paucity of material, rendering selection less easy where so many are worthy. We cannot doubt that in order of chronology the first name to be honored is that of Moses, as the author of the most complete and detailed system of hygiene in ancient times. His rules, given as part of the Divine Law, are of course mixed up with religious

ceremonial, both as being appropriate to the age and to the nation for whom they were intended, and also as being more likely to be followed when made in that way a part of the religion of the people. We may be pretty well sure that the code of Moses was the outcome of the wisdom and experience of long past ages. "Nemo fuit repente turpissimus," so also "Nemo fuit repente hygienicus." Be that as it may, however, one cannot but admire the excellent precepts laid down for the cleansing and purifying of house and camp, for the security of pure water, for choice of good and wholesome food, for the isolation of the sick and the unclean, for the destruction of refuse, etc. Some of the rules we may smile at now-a-days, as being a superfluity of precaution, and it is true that with advance of knowledge we can see that certain of them were unnecessarily sweeping in character; but still it would not be too much to say that a fairly strict adherence to the Mosaic law would have preserved mankind from many of the disastrous plagues which have afflicted it. The history of the Jews themselves illustrates this point. Of old, when a pestilence visited them, it was always represented, and probably with perfect truth, as a punishment consequent upon the breaking of the law, a statement which may be frankly accepted either by those who maintain the special intervention of a Divine Providence, or by those who regard it as a strict consequence following on antecedent cause. In later times, and especially during the Middle Ages, the Jews enjoyed a remarkable immunity from outbreaks of epidemic disease, an immunity which still distinguishes them in our own time. Several causes have combined to bring this about. 1st. They are generally temperate and frugal. 2nd. They still in the main follow out the Mosaic law with regard to their food, their meat being carefully examined and selected for its freedom from signs of sickness or parasites, nothing but pure (or kosher) meat being used. And 3rd. By reason of the periodical purifications which take place in their dwellings, as a part of their religious rites, which purifications extend to most minute particulars, so minute as to render it hardly possible that disease germs should lurk in any part of the dwelling. So little, however, was the real cause of their healthiness appreciated by our predecessors in the bad mediæval times, that it was held an irrefragable proof of their demoniac machinations, which led them to poison the wells which supplied the Christian community with water, their bigoted

enemies not stopping to consider that it would be much against the interest of the Jews to kill or harm those from whom, by commerce, they gained their livelihood. But, indeed, our own time furnishes the exact counterpart of this cruel and unreasoning tyranny, not merely in the savage outrages perpetrated by the rude and ignorant populace of Russia, but in the disgraceful *Juden-hütze* which has stained the name of civilized Prussia, and was led by—save the mark—the chaplain of the Court itself!

Let us turn now to the classic records as they are called—that is, the writings that remain to us from the Greeks and Romans. Considering how many men must have written in those times, how general knowledge and the art of writing was, we have to lament the paucity of the literary remains that have survived. How we curse the fanatical zeal of Omar, who burned the library of Alexandria, and still more the senseless stupidity of the monks of later days who scraped out the writing from priceless manuscripts to write missals and the like in their place! As might be expected, it is to the Father of Medicine, the great Hippocrates, that we owe the most of what we have left of Greek hygienic literature, although we must admit that even in Homer there are traces of hygienic knowledge, and that there the disinfecting powers of cleansing fires of sulphur are fully recognized. It is a remarkable fact that one of the chief books of Hippocrates relating to hygiene—viz., that on “Air, Waters, and Places,”—is one of the few about the authorship of which no doubt has ever been raised. Like the code of Moses, it was probably a summary of the already existing knowledge of the subject, supplemented and extended by the experience of the great physician himself. Another name that deserves remembrance is that of Xenophon, whose triumphant retreat was no less a hygienic than a military triumph; and there is no doubt also that Alexander the Great was a master of the art of hygiene, to have taken his force so far with so little loss. Nor ought we to omit the name of Herodotus, one of the preceptors of Hippocrates, and the first to introduce gymnastics on scientific principles, not only as a curative, but also as a preventive measure. The works of Asclepiades, who boasted that he would never be sick, and did, indeed, die of a fall, and those of Aretæus, doubtless contained reference to preventive medicine; whilst those of Galen, which extended to 300 volumes, the majority of them now lost, furnished many of the precepts on which later hygiene was based. On the other hand, the myth which makes Health, or Hygieia, the daughter of Asklepios (whom we call Æsculapius) no doubt arose from an instinctive perception of the value of medical science in preserving health as well as in the cure of disease. We may also be permitted to believe that the honors paid to his sons Machaon and Podalirius were due, at least in part, to their hygienic foresight as well as to their medical and surgical skill. The famous line of Homer shows the estimation in which the military surgeon of those days was held, and the consternation that fell on the Grecian camp when Machaon was wounded:—

Ἴητρος γὰρ ἀνὴρ πολλῶν ἀνταχίους ἄλλων,

Which is thus rendered by Pope:

“A wise physician skilled our wounds to heal,
Is more than armies to the common weal.”

Would that modern commanders had an equally just and appreciative estimation of the services of the best abused but most beneficent of professions. I may mention that the above line of Homer has been selected as the motto for the medal in military surgery, founded by the liberality of the late

Mr. Nathaniel Montefiore, and awarded every session at the Army Medical School, Netley. Besides the writers already quoted it would be unjust to omit the name of Aristotle, whose writings include important hygienic precepts. The praise of health was also sung in an ode of Ariphron, who calls her *πρεσβίστη μακαρῶν*, eldest born of the blessed, and also by Isocrates, one of the purest of Greek writers, whose line *Ἡ περὶ τοῦ σώματος καὶ τῆς ψυχῆς ἱγίεια*, has been adopted as the motto of the gold medal founded at Netley in memory of Edmund Alexander Parkes. The general life of the Greeks was eminently hygienic, being mostly outdoor and under favorable conditions, persons even of high position taking part not only in active occupations but in labors that might be even considered menial by the unthinking. The honorable place that athletic games held is a point of resemblance between the Greeks and our own countrymen that ought not to be lost sight of. Nothing is more conducive to health of body and mind than active exercise in the open air, and the splendor of Greek literature, art, and knowledge is a sufficient answer to those who are afraid lest athletics should develop the muscles of our youth to the detriment of their brains.

Among the Romans the care bestowed upon the provision of pure water—with which is connected the celebrated name of Frontinus, as *Curator Aquarum*—and their elaborate system of drainage, prove that they had correct ideas on some of the fundamental questions of hygiene. Their fondness for bathing and extensive establishments for that purpose remain monuments of the next to godliness which even at this distance of time we, with all our boasted civilization, have been unable to emulate. The more recent discoveries in the Campagna have still further shown that they were fully aware of the conditions which alone could make that now pestilential region habitable, as a system of subsoil drainage has been revealed that is a reproach to the ignorance and supineness of modern times. Nor was Rome the only city of antiquity that was efficiently drained, for we have evidence of it at Agrigentum at least; but Rome was certainly among the oldest of which we have actual remains, the beginnings of its great cloaca going back at least five and twenty centuries. Another direction in which the Romans showed great knowledge of the principles of hygiene was in the management of their troops on the march and during war. The rules for encampments given by Vegetius are excellent, and to the great care shown for every detail of sanitation must be attributed the comparatively small loss which the armies of the Romans appear to have sustained. We may say, indeed, of classical times generally that there was a remarkable absence of devastating epidemics, none of those on record approaching in fatality and intensity the great plagues which swept over Europe down to quite modern times.

In taking a cursory retrospect of the Old World in its medical aspects, I should be inclined to say that on the whole its medicine was as much preventive as curative. It is probable that such a proposition would be combated; but, in spite of the treatises that have survived in curative medicine and surgery, and the long list of medicaments that we find, for instance, in the works of Galen, there was probably as much, if not more, done in the preventive line as in the simply curative. The motto of the time might have been, “*Venienti occurrere morbo*.” Two things seem to indicate this:—1. There was a dread and impatience of disease, so much so that men were known to commit suicide to escape it; like the aged Indian who slew himself at the tomb of Achilles, for fear he should die

of disease, from which he had through life been free. 2. The sentiment of pity for the weak and the oppressed appears to have been absent; there was the same tendency as we find among animals and among savages to hold a sick man of little account, as useless to the State, and the sooner got rid of the better. Hence, perhaps, the curious fact that we have no record whatsoever of public hospitals or infirmaries for the sick poor during the classical period—the earliest being as late as the reign of Justinian.

From the time of the decline and fall of the Western Empire the progress of hygiene appears to have been arrested. Some few of the treatises of the Greek and Latin physicians survived, others were known only as translated from the Arabic, etc., whilst the wholesome traditions of the hygienic life of Greece and Rome appear to have decayed, and we pass into a dark and dirty period when fanaticism usurped the place of religion, and dirt became the odor of sanctity. The Hermits of the Thebaid became the types of all that was holy, and so framed their lives and manners as to be as much as possible the antithesis of the heathen. The heathen led an active and healthy life, the Christian fanatic led a life of mooning and inaction; the heathen washed himself and his clothing, the Christian forsook cold water and wore his clothing till it fell off his body from sheer rotteness. The picture of the thousand years which elapsed between the downfall of Rome and the final capture of Constantinople, as drawn by Michelet in his "Sorcière," is one of the most striking as well as disgusting that can be conceived. "Pas de bain," he says, "pendant mille ans!" Can we wonder at the plagues which devastated Europe? Is it astonishing that the "Black death" cut off two-thirds of its inhabitants? Although the revival of learning was partly instrumental in arousing the nations to a sense of their degraded condition, yet the change was by no means great, even down to much later days, and it is humiliating to think, from the accounts of Erasmus and other visitors to our shores, that our own country remained long pre-eminent in Europe for dirt and disease. Hardly a decade passed without visitations of some foul malady until the cleansing fires of the great conflagration of London in 1666 appear to have extinguished the last vestiges of those old and dreaded enemies. It is true that even then we were far from being free from epidemic disease, and that we are still open to its ravages; but the forms of disease which have shown themselves since the great plague are of a type, if not entirely different, still of a kind and under circumstances which have been more understood, and the causes traced more certainly to particular conditions. But one can easily imagine how different the case of Europe might have been could the hygienic knowledge collected during and before the classic period have been carefully put together, formulated, and acted upon by the succeeding generations. As it is, whatever may have been written in the Middle Ages, was either a mere re-echo of the classic writings, a copying of the Arabian physicians, or a farrago of nonsense into which spells and magic largely entered. When a fresh interest began to be excited, and men began slowly to perceive that the elixir of life was a vain imagining, their minds turned more to actual observation, and among other things the science of dietetics attracted much notice. The older writers had already written much on diet, and even Hippocrates had pointed out the close relation between food and work, a relation which has been fully recognized only in our own generation. Various treatises on food and regimen were written later, of which the two that might claim notice are

the one entitled "Tacuinus Domus," or "Tables of Health," published under the name of "Elluchasem Elimithar," and written, it is said, by two Jewish physicians at the request of Charlemagne. This is a curious old book, and very "rarely met with," as remarked by Mackenzie in his "History of Health," "except in public libraries, which is no great loss, being but a mean, perplexed, and whimsical performance, and scarce worth taking notice of, but only because it happens to be sometimes quoted by the learned." We possess a very fine copy of this book, which is a beautiful specimen of the printing of the early part of the sixteenth century, in our library at Netley. It is quaintly illustrated throughout with woodcuts of much spirit, representing every article and operation mentioned in the book which it is possible to illustrate. But the most celebrated mediæval work on the subject is undoubtedly the renowned "Regimen Sanitatis Salerni," the code of the famous university of Salerno, which is believed to have been compiled by John of Milan in 1099. So much was it esteemed that it was called the "Flower of Physic:" "Hoc opus optatur, quod flos medicinæ vocatur." Haller enumerates twenty editions, and it was translated into various languages—among others into English by Paynell (1579 and 1609) and by Dr. P. Holland, whose version is the best known. It was also the subject of numerous and voluminous commentaries, such as that by Arnoldus de Villa Nova, none of which, however, added much that was valuable to the original. We may well believe that this Code of Salerno is a summing up of the hygienic knowledge and experience of the time, most of it probably borrowed from the ancient writers, and suited to the habits of the age. Some of it is no doubt fantastic, but much of it is sound sense. Some of the precepts might well fit many towns of the present day, the metropolis among others:

"Lucidus ac mundus sit vitæ habitabilis aër,
Infectus neque sit, nec oleus fœtore cloacæ."

Dr. Holland's translation is not very faithful; some may render it this way:

"Dwell in air both clear and pure,
Free from taint or smell of sewer."

I do not know, however, if our friends of the Blue Ribbon persuasion would quite approve of the next precept:

"Si nocturne tibi noceat potatio vini,
Hoc tu manè bibas iterum, et fuerit medicîna."

Which I take the liberty of rendering thus:

"If overnight your drink has hit you,
Take a hair of the dog that bit you!"

Talking of dogs, I am sure all would rejoice if the receipt for the cure of a mad dog's bite were only efficacious, as it is certainly simple, and Dr. Holland translates it thus:

"A mad dog's byting may recured be,
With onyans, hony, vinegar, these three."

But we must not dwell any longer on this quaint book, although it was long the basis on which works on hygiene were founded. A list of writers who followed, more or less obscure, is given by Mackenzie, in his "History of Health," and by Sir John Sinclair, in his "Health and Longevity." Indeed, it may be said that no writings on science during the dark period were worth notice, except those attributed to our own Roger Bacon.

One of the first really practical writers on the subject of hygiene was the well-known Ludovico Cornaro, a noble Venetian, who, after a youth of intemperance and excess, reformed his ways and kept so strict a watch over his diet and habits, that he prolonged his life to the age of 100 years, dying in April, 1566. Twelve ounces of solid food

and fourteen ounces of liquid, in this case wine, were all he allowed himself, but then he led a life that was less life than mere vegetation, for he was careful to avoid heat, cold, fatigue, grief, watchings, and every other excess that could hurt his health. "How," says Sir John Sinclair, "could the business of the world be carried on if every man, like Cornaro, were to begin to follow such a system at the fortieth year of his age?" Yet the value of Cornaro's treatise was very great, for it was an indisputable proof that life might be maintained, and even health, upon much smaller amounts of food than were often taken, and further, that temperance and moderation are the best resources against both disease and accident. He recounts how he had been upset in a carriage, and been in consequence severely bruised and had an arm and leg dislocated. The doctors wished to bleed and purge him, but he, confident in his temperate habits, desired merely that his limbs should be set and he himself be let alone, after which he made a rapid and complete recovery. The advanced age to which he lived, and also the great ages of Pope Paul Farnese, Cardinal Bembo, and the Doges Lando and Donato, whom he cites, all of whom were men of regular and temperate lives, contrast remarkably with the short lives of the average of men of the time, old men being very rare, and even those who had passed the half century uncommon.

Various writers followed Cornaro, few of them of much note, save the famous Jerome Cardan, one of the most learned of the physicians of the Renaissance, but somewhat whimsical in his hygienic views. He opposed the views of Galen, and in particular objected to exercise that caused the smallest amount of fatigue or perspiration, or accelerated the respiration. He considers it to be a proof that Galen was wrong, seeing that he died at the age of seventy-seven, which, Cardan says, cannot properly be considered old age. Cardan, however, died himself a youth of seventy-five! He adhered to the principles of Cornaro in diet, and showed that he understood to some extent hereditary influence, as he considered that one of the chances of living to a great age was to be descended from a long-lived family.

Of the other writers of the period I will only refer to Thomas Philologus, of Ravenna, on account of his strong protest against intramural interment, thus anticipating by some three centuries the happily fruitful labors of our distinguished countryman, Edwin Chadwick.

The next writer of eminence was the celebrated Sanctorius, a native of Istria and a professor of Padua. He wrote a work on health, entitled "*Medicina Statica*," and he also began the era of exact observation by his well-known experiments with the weighing-chair, by which he endeavored to show the weight of the insensible perspiration. His experiments were very crude and inaccurate; but they were in the right direction, and his work may be considered as marking an epoch in the advance of scientific observation. The aphorisms in his book are couched in quaint, and even fantastic, language, but many of them are sound when stripped of the vagueness and mannerism of the time. He is particularly severe upon a certain "*Staticomastix*," who had criticised him, and had asserted that a plentiful perspiration did not take away from the body one ounce of weight.

The writers from the time of Sanctorius down to the end of the seventeenth century call for little attention, as they seem to have added but little to the knowledge of the time. The remarkable physical discoveries of the close of that century and throughout the whole of the next certainly paved the way for more exact observation in medi-

cine, both in its purely medical and its etiological aspects. Accordingly, we have the observations of Boerhaave and Haller, and a host of other names of distinction, all representatives of progressive medicine, either directly or indirectly connected with the advance of hygiene. Sketches of the various writings of this and preceding periods are given by Mackenzie in his "*History of Health*," by Sir John Sinclair, and by Hallé in his long article on Hygiène in the "*Encyclopédie Méthodique*." And I may here pause for a little to consider the name of the science which we have adopted. It has been objected to that we have taken a foreign word when an English one would do, and that there is no reason why the plain word "health" should not answer our purpose. To this we may reply that the foreign word better defines the science or art, and is less likely to lead to confusion; that the word is now adopted and used in every country of the world, and is therefore common property; and that by its use we accomplish the same end as when we apply a scientific name to a disease, or to a plant, an animal, or a chemical compound. Each of these, under its scientific name, is easily recognized and accurately described. The word "hygiene" itself is derived from the Greek *ἱγίαινα*, "I am in good health," and was apparently first definitely used by Ambrose Paré, according to Littré. Its use in this country was not general until quite recent years, the expression "medical police" being more usually employed. In Germany the kindred expression "*Sanitäts-Polizei*" was adopted, as well as the more truly Teutonic word "*Gesundheitspflege*;" but now the word "hygiene" (formerly written "hygieine") is coming into regular use. There is therefore some advantage in having a common title for our science, even although it be of foreign origin. But, after all, a good half of our tongue is of foreign origin, and as it is one of the most assimilative of all the languages of the earth, we need not reject a word that has much to recommend it on mere grounds of sentimental nationalism.

It is a little difficult in a necessarily restricted lecture to convey any exact idea of the way in which modern hygiene became formulated into so much of a science as it can at present lay claim to; but I will attempt to make a brief sketch of its more salient points. In the eighteenth century there were several important questions inquired into, and to a large extent solved, of which the chief were (1) The influence of air as a factor in the spread of disease; (2) the true cause and prevention of scurvy; and (3) the prophylaxis of small-pox. Taking the last first, we may say that the introduction of inoculation was a most important step, even although we must admit that it introduced a greater danger to the community at large than could be compensated for by the protection to individuals. But it was the first step on the road which led at the close of the century to vaccination, one of the most signal triumphs of preventive medicine, and in our own time to the magnificent results obtained by the renowned Pasteur, results which seem pregnant with so much hope for the future of our race.

The inquiry into the causes of scurvy was another step in advance, of the most signal importance. No one in the present day can form any idea of the ravages that terrible disease produced. All long voyages were imperilled by it, whilst the very existence of England depended upon her fleet, which had frequently to return to port absolutely crippled with scurvy, in some cases as many as ten thousand men being landed from the Channel fleet helpless. Although so far back as the

seventeenth century the efficacy of fruits and fresh vegetables as preventives had been surmised if not actually noted, it is really to the renowned Captain Cook that the credit is mainly due of having established this important fact. That eminent navigator never lost an opportunity of taking on board fruits and fresh vegetables whenever he could, and the result was that he was able to bring home from a lengthened voyage crews in almost perfect health and condition, a thing never before known. It took many years, however, to impress this fact sufficiently upon the authorities, and it was not until 1796 that the medical officers of the navy (among whom was the renowned Sir Gilbert Blane) obtained the regulation ordering lime-juice to be supplied to our seamen. The effect was magical; scurvy lost its terrors, and it may be that the supremacy of England at sea during the Napoleonic wars was in part owing to the improved condition of her seamen during that gigantic struggle. We have still a monument of the extent of the disease in the immense naval hospital of Haslar, the largest in this country, which was built of such dimensions mainly to admit the extraordinary number of scurvy patients which were being continually landed from our fleets. We have not yet got entirely rid of this enemy, but I think we know now how to combat it, in spite of heretical opinions which find expression from time to time.

The recognition of foul air as a factor in disease was certainly begun in the last century, when the brilliant discoveries in pneumatic chemistry made by Lavoisier, Cavendish, Priestley, Black, and Rutherford threw such a flood of light upon a previously obscure subject, and opened the whole immense vista of the boundless science of modern chemistry. It was only then that the physiology of respiration could be even partially understood, and the changes recognized which take place in the respired air from the lungs of man. The great disaster of the "black hole" of Calcutta, and the terrible effects of the gaol fever, investigated by Howard and others, pointed to foul air as a main factor in the propagation of disease and death; and this was further corroborated by the observations made by military surgeons that outbreaks of typhus (or putrid fever) were most rapidly arrested when troops were encamped and scattered widely over the surface of the ground. It was reserved for the latter researches of Neil Arnott and other hygienic observers of the present century to prove the still more important fact that foul air is the main cause of the still more general and fatal class of destructive lung diseases, which in this and in other lands cut off so many of the brightest and the best.

Another important discovery of the last century was the determination of the cause of the well-known lead colic by Sir George Baker. This opened up the large field of metallic poisoning which has received so much elucidation and proved of such importance in reference to the water-supply of large communities.

In the present century we have to point to the establishment of the fact of the water carriage of disease, with which the name of Snow is so honorably associated, the differentiation of continued fevers by Stewart and Jenner, and their connection with the poison of infected excreta by the labors of Budd and other eminent men. To those we must add the elaborate investigations into the modes of propagation of cholera, dysentery, and other tropical diseases, and the means by which scarlet fever, diphtheria, etc., are carried from place to place by various channels of communication. It would be unadvisable, even if it were possible, to enter into details on these points, but there is one branch of the subject on which we

must dwell for a little. No inquiry can assume a scientific form unless it has a numerical basis to work upon, and therefore it behoves us to note the starting-point of such a basis in hygiene, if we can find it. This we do find in the collection of statistics, a beginning of which was made a long time ago in the bills of mortality kept in this country. We know how imperfect those were, and how even the population of this country was not correctly known until within the lifetime of men still living. But still beginnings were made, and the question taken up more and more enthusiastically by enlightened men, until at last the Government Statistical Department was formed, and that remarkable series of reports begun which will immortalize the name of William Farr. From that time the future of hygiene was assured; for there was sound ground to work on, and if we add to that the valuable reports on the health of towns published by the Commission of which the present Duke of Buccleuch was president, we shall have stated some of the most important foundations of modern sanitary science. Those reports disclosed a state of things little dreamt of, and the statistical returns compiled by Dr. Farr showed how much the life and health of the nation were dependent upon the conditions in which its individual members were placed. The establishment of the General Board of Health, under Mr. Chadwick, was one of the valuable outcomes of this remarkable movement. Although the original Board of Health was brought to an end in 1854, yet its work has been continued and expanded under Mr. Simon, his colleagues and successors, in spite of many difficulties and obstacles.

The part which the public services, such as the Army and Navy, played in the progress of hygiene was very important, as might indeed be expected; for under no other circumstances could bodies of men be so well observed, and the effects of surroundings and conditions upon health noted. Accordingly we have a long roll of names connected with those services which must ever be remembered with honor; in the Navy we have such men as Lind, Blane, Trotter, Burnett, etc.; and in the Army, Pringle, one of the most philosophical physicians who ever lived, Brocklesby, Fergusson, McGrigor, and a host of others. The labors of the late Sir Alexander Tulloch, Deputy Inspector-General Marshall, and Assistant-Surgeon (now Surgeon-General) Balfour, in collecting and arranging the army statistics, were of the highest value, and it is not too much to say that the publication of the first army medical statistical report marked an epoch in hygiene, especially in that part that deals with climatology. It exposed the fallacy of the common notions of acclimatization, of the advantages of a seasoning fever, and similar ideas. It showed also that it was possible for men of temperate habits and in hygienic conditions to live and thrive in the tropics, whilst the death and sickness that were unfortunately so common were due much more to the ignorance and folly of man than the influence of climate in any form. The truth of that is to be seen now when life in the West Indies is actually healthier, especially for young soldiers, than service at home, whereas sixty years ago a tour of service there was looked upon as almost a sentence of death. It is true we have still yellow fever to combat, but we know now much better how to deal with it when it does come, and how to obviate its invasion when it is threatened. The army medical statistics are continued now yearly, but it is a matter of regret that they have been allowed to be published in so abstract and undetailed a shape as to deprive them of much of their utility. It is to be hoped that this mistake may be remedied, and that the

saving of a trifling sum, which is said to be the reason, may be recognized as a truly false economy. But perhaps the most remarkable contribution the Army has made to sanitation has been by the evidence given to the Royal Commission of 1857, which met after the Crimean war to investigate the causes of the sickness and mortality of our troops. The results of that Commission are well known, and from its publication may be dated the reforms which have been productive of much advantage both to our own and foreign armies, and to the civil population as well. The paramount influence of foul air in the production of lung disease was proved to demonstration, and the art of ventilation was placed upon a secure foundation. The Barrack Hospital Committee, of which Dr. Sutherland and Captain Douglas Galton were the active members, laid down a series of regulations for the construction of barracks and hospitals, which have been followed with the utmost benefit both at home and abroad. Following this came the Indian Commission, which did for that vast dependency what the Home Commission had done for the rest of the empire. The mortality in India was found to be inordinate, and it was equally clearly traced to insanitary habits and surroundings. To recognize an evil and its cause is half way to curing it, and after a lapse of a quarter of a century we can point, not certainly to perfection, but to such an improvement as might fairly at one time have been looked upon as chimerical. The death-rate of the army at home is only two-fifths of what it was before the Crimean war; the death-rate in India is only one-third, and the death-rate in the West Indies one-tenth.

In civil life it has recently been shown that the improvements of later times have resulted in a diminution of 2 per 1000 in the general death-rate, and with the knowledge we now have of the causes of disease we may be sure that a general death-rate of not more than 15 per 1000 may be confidently looked for. We have not yet got rid of the fatal endemics in our midst, but they are in some directions diminishing, and we have good hope for the future; whilst it seems probable that neither cholera nor any other introduced pestilence could establish a foothold in our land. The remarkable immunity of soldiers and prisoners in the last epidemic shows what can be done when people can be compelled to lead fairly hygienic lives.

I might extend this lecture by reference to the various theories of disease propagation, but time will not permit of it, even if it were otherwise desirable. I may, however, say that no one theory yet promulgated completely satisfies the requirements of the case, and that there may be some basis of truth even in the most conflicting views. So much has been done hitherto, and so much activity is being shown in investigation, that we cannot fail ere long to find the key to many of the mysteries that now baffle and perplex us. It is quite clear that it is only by a knowledge of the causes of disease that hygiene can be advanced, and that it can never be in any way perfected without a complete system of etiology; and we are at present in this position, that practical hygiene has to some extent outstripped the knowledge of disease causes. We look, therefore, anxiously towards the pathological investigations of the time, and we deeply deplore the well-meaning but misguided zeal which is at present placing such grave obstacles in the way of the only means by which true science can advance—namely, direct experiment.

Although there are many names I might refer to as great writers in hygiene, abroad as well as at home, there is one which we cannot omit in a lecture like this, more especially as it is the first delivered

in this museum which has been founded to his memory. Edmund Alexander Parkes did more than any other man in this or any age to make hygiene a positive fact, a practical science, based upon not only philosophical conceptions but actual experiment. Starting in life as an army medical officer he was able to produce during his short service in India and Burmah works upon dysentery and cholera, which will always be of the greatest value. Retiring into civil life he became eminent as a physician and teacher, and in 1855 he undertook the organization of the hospital at Renkioi, in the Dardanelles, which was a perfect model of successful hygienic administration. Struggling with distressing and dangerous disease he continued to lead a life of intellectual activity not often accomplished by the most robust; and when, in 1860, the Army Medical School was established by Lord Herbert, of Lea, Sir James Clark had no hesitation in advising that Dr. Parkes should be secured if possible as the Professor of Hygiene. How excellent the foresight of that eminent physician was we all know, for Dr. Parkes was not only the first professor of the science in this country in point of time, but also the first in every sense of the word. The publication of his well-known "Manual of Practical Hygiene" gave us for the first time a work on the subject, which was not merely a string of opinions and surmises, but at every point brought opinion to the test of figure and experiment, where it was possible, and thus laid the foundation for a real science in the future. Similarly with his teaching he pressed upon the Government to establish practical laboratories for his pupils, where they could do for themselves as much of the experimental work as time and opportunity allowed; and he impressed upon those who studied under him the necessity of testing everything by actual investigation and bringing all statements to the proof of figures before accepting them as true. There was never probably a man of calmer and more judicial mind, a man more rigidly critical of his own work, or more kindly disposed to allow every credit to the work of others. Having known him personally for many years, during thirteen of which I was his assistant and colleague, I can bear confident testimony to the exceeding beauty of his character, in which "sweetness and light" were never more truly displayed, and the scrupulous accuracy and care with which every investigation of his was carried out. The science of hygiene could have no purer and better founder and its votaries no brighter and more spotless example.

Address

ON

EYE SYMPTOMS IN DISEASES OF THE SPINAL CORD.

Delivered before the Ophthalmological Society June 7th, 1883.

By W. R. GOWERS, M.D., F.R.C.P.

MR. PRESIDENT AND GENTLEMEN—In the memorandum which, at the request of the Council, I have drawn up to serve as a guide to the discussion this evening, I have mentioned certain points regarding two classes of eye symptoms met with in spinal disease, to which it seemed to me, the attention of the Society might with advantage be chiefly directed. These are "optic nerve atrophy" and "internal ocular paralysis." These topics do

not comprehend the whole of the subjects announced for discussion. There are many others, such as optic neuritis, nystagmus, and palsy of the extra-ocular muscles, which equally deserve attention. But optic neuritis is extremely rare in association with spinal disease, the meaning of nystagmus is uncertain, and the subject of the palsies of the external muscles is so large that, while we shall, I am sure, welcome any new facts regarding these points which may be brought forward, it seems better to reserve their special discussion for a future day, and to consider to-night those topics on which we have all had some experience, and about which our knowledge is sufficient to define our ignorance, to indicate the new facts we most need, and the direction in which they must be chiefly sought.

The two subjects to be considered accord conveniently with the composition of our Society. Optic nerve atrophy, affecting vision, falls chiefly under the notice of the ophthalmic surgeon; while the most common intra-ocular palsy, that of the iris, causing no symptoms of which the patient is aware, comes as an isolated eye symptom under the attention of the physician. At the same time, the ophthalmic surgeon, with his exact study of all the morbid elements in the eye, is able to correct and supplement the observations of the physician on intra-ocular palsies, and the medical observer can perhaps supply facts regarding some points connected with atrophy which rarely come under the ophthalmic surgeon's notice.

Two general facts respecting these symptoms deserve attention. The first is that we must regard them as associations, and not effects, of the spinal lesion. The evidence of this is: (1) That disease of any nature may exist in any part of the spinal cord without the occurrence of ocular symptoms, if we except the very rare paralysis of the dilators of the pupil in disease of the sympathetic tract in the cervical region. (2) The ocular symptoms, which may be absent when the cord disease is advanced, may exist in extreme degree when such disease is in a very early stage. (3) With the single exception of the sympathetic symptoms just mentioned, we know of no anatomical connection or functional mechanism by which the spinal cord disease can produce the ocular symptoms.

The second general fact is that these associated ocular symptoms are always the result of degenerative processes, and their presence shows that the cord disease is also essentially degenerative in its nature. In many cases we do not need the eye symptom to tell us this. The slow, progressive character of the spinal symptoms is sufficient evidence of the fact. But it is not always so. Degenerative processes of the cord sometimes present sudden exacerbations which may conceal the nature of the underlying process. In these cases the eye symptoms give us information of the highest importance. Their significance in this respect is not confined to spinal disease, and it is difficult to exaggerate the practical value of symptoms which, so readily ascertained, at once put us on the track of the morbid tendency from which a patient is suffering.

It may seem surprising, numerous as are the degenerative diseases of the spinal cord, that the chief association of eye symptoms should be with one of them alone, with locomotor ataxy, tabes dorsalis. But recent pathological discoveries, if they have not penetrated the mystery, at least enable us to comprehend it. As long as ataxy was believed to be a disease, limited to the posterior columns of the spinal cord, the association with it of a peripheral degeneration in the optic nerve was an anomaly. But the brilliant researches of Pier-

ret, confirmed as they have been in part by Déjerine, and anticipated in a slight degree by Westphal, have enlarged, and by enlarging altered, our conception of the malady. Pierret has shown that the degeneration in the optic nerve is not the only peripheral lesion, and that that in the cord is not the only central change in this remarkable disease. He has demonstrated that there is, often at least, an independent degeneration in the cutaneous nerves, commencing in their extremity, to which the optic change is strictly analogous. He has shown, moreover, that there may be a degeneration at the central termination of the optic as well of other cranial nerves analogous to that in the posterior columns of the cord. He has thus enlarged our conception of the affection from a limited disease of the spinal cord to a "wide sensory neurosis," as he aptly terms it, in which the optic nerve atrophy falls into its definite place. The relation which the intraocular palsy bears to the other symptoms of the disease is a point to which I shall return presently. To what extent the degeneration ordinarily preponderates in the central or in the peripheral sensory tracts, only future observation can show. At present we have no means of ascertaining during life the occurrence of the peripheral spinal or the central optic changes. We must still therefore in our clinical study content ourselves with observing the relation between the two which we can recognize.

What proportion of cases of primary atrophy of the optic nerves are connected with spinal disease? So rarely is atrophy associated with other lesions, that the question may practically stand, In what proportion of the cases of atrophy are there indications of ataxy? As the earliest of these, the loss of the knee-jerk may be conveniently taken without risk of more than the most trifling error. The answers which have been given to the question have varied between wide limits. It is only from ophthalmic surgeons that an answer can be looked for, and the combined experience of the members of this Society would certainly yield a result very near the truth. For my own part I will only venture on one very general statement. It is certain that atrophy may precede the symptoms of ataxy which bring the patient under the physician's care. I have seen one case in which the atrophy existed for twenty and another in which it existed for fifteen years previous to the locomotor symptoms. But we know that the loss of the knee-jerk may exist for an almost indefinite time before locomotion suffers. It has not, I think, yet been proved that atrophy ever precedes the loss of the knee-jerk or lightning pains in the limbs, and we are not justified, in an inquiry into facts, to assume that any case will be followed by spinal symptoms in which none are present at the time of observation.

The converse question—In what proportion of cases of tabes does optic nerve atrophy occur?—is one to which an answer is difficult to obtain. It is difficult to obtain because the optic and spinal symptoms tend to separate the patients, and often to keep them separate. My own statistics yield about 20 per cent. of atrophy, but I think it is probable that this has been increased by accidental circumstances, and that the estimate, which I gave some years ago, of 15 per cent., will not be found far from the truth.

The period of the disease at which atrophy commences is a point of very great practical importance. For the purpose of ascertaining facts, we may conveniently divide the course of the disease into three stages—first, in which there is no affection of the patient's gait; the chief symptoms are the loss of the knee-jerk, rheumatoid

and lightning pains, and often unsteadiness in standing with bare feet, toes and heels together, and closed eyes. Second, in which there is a distinct ataxic gait, but the patient is able to walk alone or with the aid of a stick. Third, in which the patient is no longer able to walk except with the assistance of another person. There is no doubt that it is common for atrophy not only to commence, but to advance to a considerable degree, in the first stage of the disease. In the cases which have come under my own observation atrophy has commenced twice as frequently in the first as in the second stage, and very rarely in the third; but I think it would be found from a comparison of the experience of ophthalmic surgeons and of physicians, that the real excess in the first stage is still greater than this. Moreover, I think that there is a peculiar relation between the symptoms, which increases the difficulty of arriving at a conclusion from partial statistics. It is that when atrophy commences in the early stage the progressive tendency of the atrophy is often strong, and that of the spinal disease is slight, and conversely when the atrophy commences later in the disease, after the alteration of gait has become well marked, the tendency of the atrophy to progress is much less marked. Of course, exceptions are not rare, but I have seen many cases which illustrate the statement. In some early cases atrophy has progressed to complete loss of sight, and for two, three, and even five years there has been no increase in the spinal symptoms, no affection of gait, even after the steady influence of vision has been withdrawn. On the other hand, in several cases, amblyopia, coming on during the second stage, has remained stationary for one or two years, and in some has even improved. For instance, a man came under treatment with the second stage well developed, but still able to walk. Vision had lately failed. There was no affection of accommodation, no distinct limitation of the fields, but acuity was reduced to 1-7th R. and 1-10th L. Two years later the spinal symptoms had increased, so that he was scarcely able to walk without help, but vision had improved to R. 1-3½ and L. 1-4½.

I have not succeeded in tracing any relation between the character of the spinal symptoms and the occurrence of atrophy. It is well known that the atrophy usually commences in one eye before the other, and sometimes reaches a considerable degree before the second eye suffers. I have not met with any case in which sight was entirely lost in one eye while the other was unaffected. Which eye usually suffers first can only be decided by the collection of cases on an extensive scale. The symptoms of the atrophy, the characters of the impairment of vision, their uniformity or diversity, constitute a problem of some practical, and still greater pathological, interest. It is frequently said that color vision becomes impaired, and the field limited, before central vision fails. Certainly, however, the field for white does not always become limited before acuity of vision is reduced. I have seen several cases in which, when roughly tested with a small object, no peripheral limitation of the field could be found, although acuity and color vision were considerably impaired. I may mention one case, in the first stage of tabes, with grey atrophy of both discs, apparently equally advanced in the two. There was a considerable difference not only in the degree, but in the mode in which vision was affected in the two eyes. In the right there was only qualitative perception of light, and even this was limited to a narrow zone around the fixing point. With the left eye only No. 16, Jäger, could be read at eighteen inches. No green field could be found. That for red was much

limited. Those for yellow, blue, and white appeared to be normal. Carefully tested with a white object, half a centimetre square, the patient's field for white was the same as my own. A year later acuity had failed still further. He could only read No. 50, Jäger. Color vision was nearly the same as on the previous occasion. The field for white presented only a slight peripheral limitation on the inner and lower part. There was no central loss. I suspect that a careful examination of the mode of failure would show that it presents many variations, just as does the loss of sensation in the legs. Pain may be lost before touch, or touch before pain. The loss may be confined to the soles of the feet, or the soles may alone retain sensibility, which is impaired elsewhere.

Irregular defects in the fields of vision are of considerable interest in connection with another question. Do the symptoms ever suggest that the process which impairs vision is greater in extent and intensity behind the eyeball than at the visible extremity of the nerve? Two cases of ataxy have been recorded, in which there was temporal hemiopia, and one of them I showed to this Society, and have recorded another in which there was a defect in each inner and lower quadrant—viz., partial nasal hemiopia. These cases suggest that the damage to the nerves reached its chief degree at the chiasma. In connection with this question of retro-ocular damage another condition deserves notice, the occurrence of amblyopia without any change in the appearance of the optic discs, or of much greater loss of sight in one eye than the other when the ophthalmoscopic appearances are slight and equal in the two. I have more than once seen this. One patient, for instance, who had no affection of accommodation, and whose discs had a perfectly normal appearance, could only read with one eye No. 2, and with the other No. 10 test type. These cases certainly deserve study.

The impairment of vision sometimes increases very rapidly. A similar rapid increase is occasionally observed in the spinal symptoms. I have more than once known a patient who could walk fairly well lose in a day or two all power of locomotion. Do the cases with sudden failure of sight, or of rapid but steady course, present any differences in the aspect of their discs from those in which the downward progress is slow? In some patients the disc is clear and excavated; in others it appears to be occupied by a grey, soft, gelatinous-looking tissue, and the vessels are sometimes slightly narrowed. Does any difference in course correspond to this difference in aspect? In the patient with temporal hemiopia the loss came on very rapidly, and the gelatinous aspect of the disc was very conspicuous. Is the colloid-looking tissue seen between the fasciculi in sections of the nerve more abundant in these cases than in others?

Regarding the connection of optic nerve atrophy with other spinal diseases, I have little to say. I have only twice seen it in cases of slight lateral sclerosis, and three times in insular sclerosis, never in progressive muscular atrophy or myelitis. Doubtless the slight frequency with which it occurs in these affections, compared with ataxy, is to be associated with the fact that they for the most part affect the motor, and tabes the sensory, nervous tracts. In general paralysis of the insane atrophy is somewhat more common, and may be an early symptom; but the question of its frequency, and the spinal symptoms with which it is associated in this disease, I will leave to those who have had larger opportunities of watching the course of the affection.

I pass next to the second part of the subject—the conditions of the internal muscles of the eye—

ball, of the iris, and ciliary muscle, which are met with in spinal disease. These conditions and their probable mechanism have been more than once brought before the notice of the members of this Society. Of the four muscular actions—contraction of the ciliary muscle on accommodation, contraction of the sphincter iridis occurring with accommodation, contraction of the sphincter iridis on stimulation of the optic nerve, and contraction of the dilator fibres of the iris on stimulation of the skin—of these actions some or all may be lost in association with spinal disease. They depend on at least three centres capable of separate action and liable to separate disease, all of which probably lie in a tract beneath the aqueduct of Sylvius below the front part of the corpora quadrigemina. The experiments of Hensen and Voelcker make it probable that the anterior portion of the tract governs accommodation, and the centre next behind it, the reflex contraction of the iris. To the outer side of the latter is a centre on which depends the reflex sensory dilatation of the iris. The efferent paths of the two former are through the third nerve. We as yet know little as to the centre and path for the contraction of the iris which is associated with accommodation. We do not know whether the nucleus for the ciliary muscle is connected with the mechanism for contraction of the pupil at the centre, or in the lenticular ganglion, or in the ganglionic mechanism within the eye. The latter is, on the whole, unlikely, and it is not improbable that the connection is established in the lenticular ganglion. If the connection were at the centre—that is, if the centre for the ciliary muscle caused contraction of the pupil by acting on the adjacent centre for reflex contraction—the pupil ought not to preserve its action on accommodation, when it no longer acts to light. But as is well known, the light reflex is lost when the associated action is preserved. The path by which stimulation of the skin causes reflex dilatation of the iris is more circuitous. The afferent impulse reaches the centre by the cervical part of the spinal cord, when the skin of the neck is stimulated, and the efferent impulse descends the cervical cord, probably passes through a subsidiary centre in the lower part of the cervical enlargement, and passes to the superior thoracic ganglion of the sympathetic, and then ascends the sympathetic to the eye.

Like atrophy of the optic nerve, paralysis of the internal muscles of the eyeball are as frequent in locomotor ataxy as they are rare in other diseases of the spinal cord. The most frequent condition is loss of reflex action to light, while the pupil still contracts on an effort at accommodation, reflex iridoplegia, the Argyll-Robertson phenomenon, as it is termed. With this is often associated, as Erb first pointed out, a loss of the dilatation on stimulation of the skin. How far the association is invariable will be presently considered. Next in frequency, but very much less common, is paralysis of all the muscles within the eye, both cycloplegia and iridoplegia, the "ophthalmoplegia interna" of Hutchinson. The rarest of all is loss of accommodation, cycloplegia, without loss of reflex action. How frequently are these conditions met with in ataxy? Of seventy-two cases of primary degenerative ataxy of which I have notes, the internal muscles of the eyeball were normal in only six; some defect existed in sixty-six, or 92 per cent. Loss of reflex action to light was the only condition in forty-eight; but to these should probably be added six others, in which action to light was very slight, although just recognizable, and one in which the loss existed in one eye only. Thus there was total loss of the light reflex in

about two-thirds, and either total or partial loss in about three-quarters of the whole number of cases. In the remaining eleven cases (15 per cent. of the whole) the pupil did not contract on an effort at accommodation, and in most of these it was clear that accommodation was also lost. In six there was total loss of accommodation and the light reflex, ophthalmoplegia interna. In two cases accommodation was lost in one eye, and action to light in both. In ten cases accommodation was lost in both eyes, and the light reflex in one only. In two cases accommodation was lost, but the action to light was perfect.

It is well known that these intra-ocular paralyses often occur early in the course of tabes, but the point deserves more exact examination. Of the seventy-two cases twenty-five were in the first stage, twenty-nine in the second, and eighteen in the third. The percentage of the cases with intra-ocular palsy was in the first stage eighty-four, in the second stage ninety-three, and in the third 100. Thus in no case, in the third stage, were they absent. These facts show that in the majority of cases (four-fifths) these ocular complications occur early, but also that cases which escape in the early stage usually suffer during the subsequent course of the disease.

Do these paralyses precede the earliest symptoms of ataxy—occur before even the loss of the knee-jerk? To prove this it is not enough to find, for instance, the loss of light reflex without spinal symptoms, because we are not justified in assuming, any more than in the case of optic nerve atrophy, that the spinal symptoms will follow. Proof of the sequence can only be supplied by the demonstration of its occurrence, by the observation, for example, of a case in which loss of the light reflex at first existing alone was succeeded by the loss of the knee-jerk. Such a case has not come under my own observation. The nearest approximation to it was supplied by two cases in which there was total loss of the light reflex and an unequal knee-jerk, and in one of these, two months later, the knee-jerk could no longer be obtained on the side on which it was, at first, the slightest.

When the light reflex is lost the pupils are often, but not invariably, small, a point to which attention has been directed by Mr. Hutchinson. In two-thirds of the cases they were below $2\frac{1}{2}$ mm. in diameter. In the remainder they were larger, 3 mm. or $3\frac{1}{2}$ mm., and occasionally 4 mm., $4\frac{1}{2}$ mm., or 5 mm. When there is loss of accommodation they are rarely very small, rarely less than $2\frac{1}{2}$ mm., and they are often 4 mm. or 5 mm. in diameter. Inequality in size is common in both conditions, and so also is slight irregularity in shape. I have not succeeded, as a rule, in tracing any relation between the size of the pupil and the other symptoms of the disease. One exceptional case deserves mention. In this, on the side on which the pupil was the smaller, there was unilateral sweating over the head and face; this may be taken as evidence of lessened action of the sympathetic, which, it will be remembered, supplies also the dilator fibres of the iris. In the conditions in which we meet with loss of the light reflex it is sometimes modified in a peculiar manner. The pupil contracts under the influence of light, but immediately dilates again to its previous size, and this is maintained, often after a few conspicuous oscillations. Does this condition pass into total loss of the reflex?

The reflex dilatation of the pupil when the skin is stimulated has risen into importance since Erb pointed out that its loss is associated with the loss of the light reflex. It still remains rather a matter of curiosity than of practical value, but certainly deserves further study. It is a phenomenon

closely allied to the contraction of arteries which may be produced in animals by the stimulus of pain. The dilatation of the pupil may be obtained by stimulation of the skin of the face as well as of the neck, and also from other parts, but the neck is the most convenient place. Erb employed the faradaic brush, but the phenomenon can be obtained with equal readiness by any other painful stimulation. The point of a quill pen, for instance, answers well. Like the light reflex, it is double; stimulation of one side causes dilatation of both pupils. It is not always easy to recognize, and is certainly sometimes absent under normal conditions, especially in persons beyond middle life. In testing for it care must be taken that the pupils are not contracted either under the influence of a strong light or of accommodation. Without doubt the statement of Erb, that this skin reflex is usually absent when the light reflex is lost, is true of the majority of cases, but it is not true of all. I have seen several cases in which there was no contraction to light, but well-marked dilatation on stimulating the skin. In these cases the pupils were large; but the skin reflex may be lost even when the pupils are not below middle size. The skin reflex may be preserved when the accommodation is lost. Thus, in one patient there was loss of accommodation and no contraction, on an attempt to accommodate, in either eye. The right pupil, 4 mm. in diameter, did not act to light, while the left, 2 mm. wide, did contract. Both pupils dilated when the skin was stimulated.

A peculiar interest attaches to the early occurrence of these intraocular palsies in tabes. Almost all the other symptoms are on the side of the sensory system. Here only have we an early lesion in motor structures. It is true the loss of reflex action may be regarded as due to a lesion on the sensory side of the reflex mechanism. But this is improbable, because the loss of accommodation sometimes associated with it can only be due to a degeneration in motor structures. It is extremely probable that the loss of the skin reflex is of the same nature. Hence, while recognizing the peculiar interest which, as Dr. Buzzard has pointed out, attaches to the coincidence of the loss of the knee-jerk and of the light reflex as early symptom of tabes, we must also recognize the difference which almost certainly exists between them, the one being due to a sensory, the other to a motor, lesion.

I have met with this affection of the intraocular muscles in no other disease limited to the spinal cord but ataxy, if I except one singular case of old-standing wrist-drop, the origin of which was obscure. In lateral sclerosis, insular sclerosis, spinal muscular atrophy, and various forms of myelitis they have been absent. Even in cases of combined lateral and posterior sclerosis, in which there is ataxy of gait, inability to stand with the eyes closed, weakness and excessive knee-jerk, these pupil states are absent; evidence, with other differences, that the process of posterior sclerosis is not the same in site or character as in ordinary tabes.

On the other hand, in general paralysis of the insane, these ocular conditions are frequent, at least in hospital cases. The examples of this disease which are most frequent among hospital out-patients present certain apparent peculiarities. The physical symptoms are the same as in the classical form, indications of spinal degeneration are frequent, especially of lateral sclerosis, but the mental symptoms are less characteristic. There is usually some mental failure, loss of memory, etc., but there are rarely the optimism, delusions, and expansive delirium, so common in asylums. It may be said, and perhaps it is true, that these are

merely cases of the classical form in an early stage, but certainly their progressive character is little marked. I have watched a few of these cases for a year and a half or two years, without being able to observe any considerable increase in the mental symptoms. In this form the affection of the pupils is almost as frequent as in tabes. Of nine cases, in all of which tabetic symptoms were absent, in six the light reflex was lost, and in one other it was lessened. In no instance was accommodation lost. Of the frequency of these symptoms in asylum cases of general paralysis I hope we shall hear more to-night.

Intraocular palsy may occur without spinal disease (as Mr. Hutchinson has shown), and such cases deserve careful study. I have notes of fifteen, in eleven of which there was loss of reflex action to light, accommodation being preserved. In four accommodation was also lost. Two patients were the subjects of epileptoid attacks, with some indication of brain failure. In four there had been slight hemiplegia, and in two of these there was also some mental change. In two there was optic nerve atrophy, unequal in the two eyes, and slight enough in one eye to establish the independence of the reflex loss. In two there was no other nervous symptom, and in the rest only slight and indefinite symptoms. Mr. Hutchinson has shown how frequently syphilis is to be traced in the past history of the subjects of ophthalmoplegia interna, and the same lesson is taught by the cases now under consideration. In no less than seven of the fifteen there was a history of constitutional syphilis; two others had had suspicious sores, and in another syphilis, although not proved, was in a high degree probable. I may mention a striking instance of this relation. A woman whose husband had had constitutional syphilis came under treatment for an attack of hemiplegia, followed by chronic mental disturbance and weakness of one third nerve. In each eye there was total ophthalmoplegia interna, with large pupils. The husband, who presented no nervous symptoms, had very small pupils, with loss of the light reflex. The relation of these symptoms to syphilis is of special interest on account of their frequency in ataxy, and of the much disputed relation of ataxy and syphilis. Like tabes, the pupil symptoms are doubtless due to a degenerative process; but we are on that account as little justified in denying as we should be in affirming a causal relationship. It is a question of fact, and not of theory as to what syphilis can or cannot cause, or at least only so far of theory as it may be necessary to modify our theories in harmony with the facts.

I regret that I am unable to offer any fresh contribution to our knowledge of the pathological anatomy of these affections; but I trust that the deficiency may be supplemented by others. I have thought it better to keep to the region of clinical observation, than to venture into the fair but infertile field of speculation as to the causes which determine the association of the symptoms. For these we must still wait for facts, and we may reasonably anticipate that they will come. In few departments of medical ophthalmology has progress been more rapid, and it may be added, in few has it been more rich in its practical applications.

A bill has been introduced in the Minnesota Senate, requiring the provision of seats for all females employed in factories and stores. Reforms which are left in monarchical England to be brought about by the humanity and good sense of the people, are enforced by law in free Republican America.

Gulstonian Lectures

ON

STERILITY IN WOMAN.

Delivered in the Royal College of Physicians, London,

By J. MATTHEWS DUNCAN, M.D., F.R.C.P.L.,

Physician-Accoucheur and Lecturer on Midwifery at St. Bartholomew's Hospital, etc.

LECTURE III.

ITS PREVENTION AND CURE.

MR. PRESIDENT, VICE-PRESIDENT, AND GENTLEMEN—As in past ages, so also in modern, sterility has been an object of great interest, of study, and of experiment. The acquisition of wealth has at all times stimulated the agriculturist, the gardener, and the breeder; and the desire of offspring has no less stimulated men and women. At no time has the subject had more importance than at present, for the growth of science and the love of daring speculation bring now on the field a class of men of trained intellect, who invade it, not to make money or secure offspring, but in search of knowledge. It is to such men that Nature opens her secrets, and the divulging of truth through them is the just pride of philosophy.

A true theory of sterility, even though it be lamentably incomplete, is of very great importance in medical practice. Thousands of women are seeking what they call cure, and their advisers should surely take care to know what they can offer in return for the confidence placed in them. According as medical men have their course illuminated by knowledge so will they be wise in advising; and if increase of knowledge, acting directly or by dispelling illusions, destroys faith in remedies, it may yet, in this negative way, add to the usefulness of the adviser. It has been said by Brodie of John Hunter that by teaching us when we are not to interfere with the ordinary course of events he has contributed more towards the advancement of the healing art than all the inventors of remedies who had gone before him.

The course and the details of the argument in these lectures point to a law or laws of sterility not yet clearly formulated; and it is to be expected that progress will be obtained from inquiries such as have been here described, as well as from investigations of the intimate state of the reproductive organs, including those parts of the nervous system which govern them or are governed by them.

Deficient reproductive energy or want of sexual vigor is a theory too vague to be satisfactory. It is only a general idea which loosely binds together, meantime at least, the items of knowledge we have acquired as to sterility. Of course it is a general idea to whose entertainment no known fact is hostile. But it is flimsy, like a ghost, and a fact might find it difficult to prove its steel; for, like a ghost, it might be cut by a sword without being destroyed or even damaged in the eyes of those who see it. Deficient reproductive energy is held to be proved by all the conditions which produce or which attend sterility in plants, animals, and man. In woman it is shown by absolute sterility, by relative sterility, by excessive production, and by imperfect production, which may be abortion, or miscarriage, or morbid pregnancy, or children diseased or difficult to rear, or destined to peculiar diseases during extra-uterine life. Deficient reproductive energy cannot be regarded as a substantive disease with specific characters, course, and remedies. It is a constitutional con-

dition, which, according to its cause, may affect a population or affect certain classes. Cold or heat may render a whole population sterile. Underfeeding or overfeeding, or premature or post-mature marriage, may cause sterility in certain classes within a population. Sterility, the result of deficient reproductive energy, is an imperfection which does not show itself by measurable, tangible qualities such as a dwarf exhibits, but by absence of function, or a stunted or otherwise imperfect performance of function.

The consideration of the great causes of sterility, exhibited as they are in their results in populations and in classes of women, makes it almost certain that local causes, whether acting as impediments to conception or as unfavorable to pregnancy and to intra-uterine life, have very little scope for operation. These local causes have a clinical interest as affecting individuals; for they have not been supposed, far less shown, to have any connection, or even accidental association, with the great causes whose scope is wide and certain. In the production of cancer of the womb there may be great operating causes, such as age and multiparity, and there may be minor local causes, such as the so-called ulceration of the cervix uteri and its injudicious treatment; and these minor causes, although doing little harm to a population or a class of women, may be of the highest practical importance to individuals.

In women, the chief and best demonstrated sources of, or attendants on, sterility are juvenility or prematurity, elderliness or post-maturity, dysmenorrhoea, and disorder of sexual appetite and pleasure. Of these the influence of age has been most fully shown, and it is that which is most under control with a view to prevention.

As in cases of constitutional diseases or of epidemic fevers, so here, the good done by prevention immeasurably exceeds, or may immeasurably exceed, any possible good by cure; and this, whether the good done is to a population or class or to an individual. The superiority of prevention is partly because the good is to a population or class, not to mere individuals. Prevention is to be, in part, effected by avoidance of unions of immature women or of elderly women; in other words, by securing that women are married at the age of nubility, or best age of marriage, with a view to fertility and the rearing of healthy children, and the safety of the mothers, and this age is fairly well ascertained to be, for a population or mass of women, not under twenty and not above twenty-five.

In the breeding of domestic animals and of animals in confinement, man can interfere easily and without restraint, except from his own interests, but it is otherwise in woman. She enjoys liberty within wide limits, and she is more or less subject to the restraint of social, moral, and religious law or custom. These restraints diminish the power of the medical adviser to guide; and, in general he can do most good by diffusing knowledge as to the prognostics from marriage entered into under various conditions.

At present the law of England legitimizes marriage at a very early, a too early, age; and it, wisely no doubt, does not interfere with late marriages. "Without the sanction," says Major Graham, "of the laws of physiology, or of common sense, a girl may—but in the present day rarely does—marry at the age of twelve, a boy at the age of fourteen, under the existing laws of England; but the consent of parents and guardians is required in certain cases where either party has not attained the age of twenty-one; and the proportional number of either boys or girls who marry under the age of twenty is happily small. The

age," he adds, "of marriage cannot be directly fixed by laws; but legislation, by prescribing the minimum age of marriage, and the age of majority, does exercise a considerable influence on good numbers of the people directly, and on all indirectly. It becomes the custom or the fashion not to marry below the age of majority. Thus in England about 9,000 young persons of the age of twenty and under twenty-one married in the year 1851; while about 139,000 married in the four years after they were of age, as it is called, or in the years of age, twenty-one to twenty-five. The age of majority is twenty-five years in France; and the age of twenty-five divided the minors from the majors in Roman law. The advanced age of majority, or of what becomes practically the lowest age of marriage, retards marriage indefinitely in many cases, and will probably be found, on investigation, to account, at least partially, for the comparatively small number of children to a marriage in France. By raising or depressing the age of majority, the Legislature then has the power to exercise considerable control over the population." These remarks of Major Graham are valuable in themselves, and indicate the view taken by a politician. The law of majority has no doubt great influence, and by it the State can modify the age at marriage to some extent; but the laws of love, of self-interest, and of social convenience are much more powerful.

The sterility of near relations, of interbreeding, or of breeding in and in, as it is often called, is generally recognized, though far from well proved in man, and forms what seems a contradiction in terms, an inherited sterility. It is believed to be shown not only by absolute sterility and its accompaniments, but also by the production of idiots and ill-formed children. Restraint by knowledge of these risks of intermarriage is no doubt a powerful preventive of sterility, but not so potent as it ought to be.

There is, as already pointed out, a sterility dependent on some inscrutable incompatibility of the parties, as in Augustus and Livia, Napoleon and Josephine. Cases like the following are not very rare, and I have actually observed them. A man marries successively three childless widows and has children by each of them. A woman is married successively, and within childbearing limits, to three men, and has children by only one of them. Such cases, if very rare, might carry little weight, but they are so common as to have occurred within the knowledge of most observant people. Sterility of this kind we cannot foresee and prevent; and religion, morals, and law continue to interdict the cure that might result from a change of husband. Unfortunately, however, among large classes—chiefly, I am told, in Wales and some parts of Scotland—custom permits, and local morals do not interdict a practice which produces many illustrations of this mutual incompatibility. The practice is called bundling, or keeping company, and consists in parents permitting daughters to cohabit with an eligible man on the understanding that, if pregnancy ensues, the legal marriage tie is made. A woman proving sterile may be deserted by her follower, and gets another with whom the result is different.

In ancient times much was known and taught regarding the avoidance of sterility, and most of it was in accord with what is still taught, but little was done with a view to the cure. The physiology of reproduction was little advanced, and its primary or elementary conditions quite unknown. When certain winds were believed to cause sterility, and fecundation was supposed to be effected by an aura-seminalis, we could not look for rationality in practice. Accordingly, such cures of

sterility as were then practiced appear to us ridiculous or fantastic.

In modern times the physiology of reproduction is comparatively far advanced, and the necessity of the physical conjunction of the male and female elements is especially recognized. But it may be doubted whether the cures of sterility are much more rational than those of the ancients, for the laws of sterility have been investigated with no great amount of success; and especially do we remain uncertain as to the physiology of the conveyance of the spermatozoa to the Fallopian tubes.

During the last thirty years gynecology has made great and rapid strides of substantial progress, and naturally sterility, as part of it, has swollen in bulk; but the growth of it has not been satisfactory, for it has not a sure foundation. While our general knowledge of sterility in woman has made little advance, and especially that part of it which might be turned to practical account, the curing of sterility has reached great dimensions. As in other departments of therapeutics, there has been a great failure of logic; the *post hoc* and the *propter hoc* have been confused—a coincidence has been regarded as a consequence. The credulity of patients and of doctors has been a basis for useless and often injurious practice.

It is scarcely an exaggeration to say that, in recent practical works on sterility, there is exhibited entire ignorance or entire neglect of the laws of fertility. Every woman from fifteen to forty-five is regarded as likely to breed. If she is sterile, a cure is at once set agoing; and if a child is not born, the failure is not debited to the nature of the case, but to the want of ingenuity in the doctor. A reputation for curing sterility is spoken of as if it were founded on substantial claims. The prevalent methods of curing sterility are founded on an implied theory that it in most cases arises from impediments in the way of the spermatozoa reaching the ovum. Without sufficient evidence strictures are assumed to exist, versions and flexions of the womb are held so to distort the interior passage as to prevent progress of the spermatozoa, cervical catarrh is believed to stop them by mechanical obstruction, or by chemically poisoning them; and for these real or imagined evils sterile women are made the subject of treatment. It is the theory of mechanical obstruction that by its simplicity and directness has possessed the profession and the public, and accordingly many operations and modifications of operations, and very many instruments have been devised to do away with the obstruction. The theory has had real rational support, in the fact that dysmenorrhœa of a spasmodic kind does, as already shown, frequently accompany the sterility, and in the supposition that the same obstruction which causes sterility by impeding the entrance of semen causes also dysmenorrhœa by impeding the exit of menstrual blood, or *vice versa*. It has had still more satisfactory support in the observation that the cure of the dysmenorrhœa does occasionally bring with it cure of the sterility.

The very zeal with which the mechanical theory of sterility has been fostered, and its treatment in many ways pursued, has led to its present decadence, and there is now increased attention paid to other departments of fertility than conception. Especially and justly, the difficulties of naturally starting and healthily continuing pregnancy are brought prominently into view. The mechanical obstruction theory has begun to shrivel, because of the impression produced by the enormous, though inexact, proportion of the failures of the attempts to cure founded on it. Even the ignorant sterile women could see that, if the theory of causation were true, there was an

easy and plain theory of cure, and they could also see that the failure of the so-called cure was prejudicial to, if not destructive of, the theory. The importance of the difficulties of pregnancy now brought into prominence will, on account of its great reconditeness, be received with no enthusiasm, such as welcomed the obstruction theory, and the physicians who entertain it can offer no such brilliant prospects of cure to their confiding patients. It is, however, a decided step of progress in a subject of great practical importance.

It is in Germany that this department of sterility has been chiefly studied, and Grūnewaldt, of St. Petersburg, is its best exponent. Recognizing the importance of this work, I take the liberty of using it to show the great incompleteness of even the most advanced accounts of the subject. For Grūnewaldt, sterility is truly never a disease, but a symptom of a disease. Nature has, he says, set no limits to female breeding other than the natural changes in the sexual organs that are observed in the senile state. Sterility is one of the most frequently occurring disturbances of function caused by diseases of the female sexual organs. In these views, and in his whole work, it is implied that sterility depends on disease of the sexual organs, including chiefly endometritis, mesometritis, perimetritis, and parametritis. The difficulties of conception, he says, have only a slight importance compared with the disorders of the more important vital processes of pregnancy, and these disorders affect chiefly the tissues of the uterus.

It would involve a useless recapitulation of the substance of these lectures were I to set about showing how partial and imperfect is that theory of sterility which makes it depend on local disorder or disease, whether the disease impedes conception or interferes with the progress of pregnancy. Taken together, the obstruction theory and this theory of Grūnewaldt, do but cover a small part of sterility, which may be described as the part affecting scattered and sparse individuals, and giving thus its importance to these individuals, and to their advisers.

The obstruction theory and the theory of Grūnewaldt make no room for that kind of prevention which we have described as of paramount importance. On the other hand, they open up great, indeed almost unlimited, fields, for the activity of curers. But the failures of curers is so notorious and the curing of sterility has so bad an odor in the nostrils of many, probably of the majority, of the best in the profession, that it is worth while to ask the question, Is sterility curable?

Before this question there comes another which is of great importance. Should sterility be cured, as it is called? That, in the interest of the community, it should be prevented I have no doubt; but, in this department of the subject, statesmen and economists have taken much interest, and I shall not meddle in it. I am of opinion also that it should, if possible, be cured. Yet a good argument may be made out for not curing it, in many cases at least. For the laws of sterility show that if it is, what is called, cured, there is a risk of some of its alternatives or attendants—morbid pregnancy, abortion, miscarriage, weakly children, excessive family, death of the mother, and others. But the practitioner hopes, by appropriate cures, to conduct his patient and her offspring in safety through these perils; and we do not, meantime, feel disposed to cavil with this perhaps over-estimated view of his rational expectations.

It will be admitted that reputation, even with well-informed medical men, is not sufficient to prove the reality of a so-called cure, and we are constantly meeting with instances of exaggerated

credulity in reported cures of young women married between twenty and twenty-five, and who had not lived three years in the married state, for it is common for such ardent young women to thus prematurely regard themselves as doomed to persistent sterility, and seek advice with a view to averting their dreaded fate. But there can, I think, be no doubt that sterility is often cured, and such cases as the following do all but absolutely prove that cure is possible, and the sufficiency of the proof will not be controverted by anyone if it is added that such cases, though rare, are sufficiently numerous to prevent by their number, apart from their other circumstances, the confusion of a coincidence with a consequence.

A. B—, married at twenty years of age, menstruated regularly since thirteen, has had dysmenorrhoea most of her life, but not very severe, has never been pregnant. Has had no uterine treatment till now, when the cervix was canalized by bougies in the usual way twenty-two years after marriage. No known change was made in her conjugal or other habits. She became pregnant at once after the treatment, and had a living healthy child at forty-two years of age. Now, five years after the birth, pregnancy has not recurred.

C. D—, married at nineteen years of age, began to menstruate at thirteen, and is regular, with pain for a short time on the first day. After fifteen years of married life has had no pregnancy. Has had much uterine treatment. Cervix canalized by bougies, and for the first time, according to her. No change made in conjugal or other habits. On resumption of cohabitation, two months after the treatment, became pregnant, and had a healthy child at thirty-five years of age. Since this birth three years have elapsed, and she has been twice pregnant.

It is, however, desirable to go further than merely prove that cure is possible, that a cure has been effected; and I believe the most important means of curing sterility or relative sterility is improvement of the general health. In the case of plants, the value of digging about and dunging is well known, and so is the value of proper exposure to the sun, and so is the value and, indeed, the necessity of good air, not the air of large cities; and the use of these, when previously withheld, is certainly curative of sterility in many kinds. The cure is sometimes, as in apple or pear trees removed from the shady side of a wall to a better exposure, accompanied by other changes, in leafage and in growth of wood, which make better general health evident to the eye. But the cure may have no accompaniment of other signs of better general health, for some London trees which are sterile have a fine outward show of healthy vigor, and it can scarcely be doubted that return to a purer atmosphere would restore their fertility, though it could do little to improve their appearance. In the case of animals, a similar influence of general health may be noted. The starving of fowls diminishes or even arrests their fertility. We cannot doubt that the agouti, released from confinement and restored to its natural habitat, would produce healthy offspring instead of dead and ill-formed; and that, similarly treated, the lioness would have cubs without cleft-palate.

In the case of woman, the restoration to, or improvement of, general health involves such a variety of considerations as renders it very difficult of treatment, and the whole matter comes as much under the care of the general physician as of the gynecologist. But it may be mentioned that special means have been recommended, and are much used, such as the waters and baths of Germany. These are of different kinds: and the Schwalbach, Spa, Franzensbad, Ems, and Marien-

bad have great reputation. That they are often of some kind of service I have no doubt, just as I daresay that horse-riding, said to be recommended by Boerhaave against abortion, may also be sometimes valuable as a remedy of that tendency.

It may well be objected that general health is too vague a term, and that it would be better to profess ignorance than to ascribe to it such important and definite a result as sterility, and it will be justly asserted that the great mass of sterile women have the appearance of good health. The difficulty of the subject is well expressed by Darwin in a passage I have quoted treating of the causes of sterility in animals. After all, I think it best, in the present imperfect state of our knowledge, to group a large number of injurious ill-defined influences under the head of general health, and to consider its improvement a means of cure. Although an animal sterile under confinement appears healthy, one cannot positively object to the statement that sterility is evidence that it is actually unhealthy, and the cure by restoration of freedom seems to confirm the view. Whatever may be the objections to the term "general health," everyone will recognize the importance of investigating the subject with a view to increasing our power over it; for it carries with it a strong influence not only towards the cure of simple sterility, but also towards the safety of the mother, the avoidance of morbid pregnancy, of miscarriage, of dead, ill-formed, and unhealthy children, and of excessive families.

Over-feeding and the production of fat are often spoken of as if they were identical; but this is plainly not the case, for many excessive feeders are not fat. What is the influence on sterility of over-feeding or feeding by particular foods without fattening, I do not know; but there are analogies which dispose the mind to suspect that influence may be thus exerted. Plants are habitually spoken of by gardeners as overfed by rich soils and manures, but they do not get fat. Mr. Thomson, recently showing me his tomato plants, pointed out some set among strong manure, growing luxuriantly in wood and leaves, but producing little fruit; others, which had been similarly placed, he had restored to due fruit-bearing, with diminished production of branches and leaves, by diminishing the contact of their pots with the rich manure. The growth of stems and leaves some may regard as the equivalent of fat in animals, but in that case stoppage of growth would be equivalent to resorption of fat, which would be driving analogy too far.

Although the injurious influence of fatness in women on fertility is universally admitted, it has not been altogether proved. But universal consent is strong evidence, and it is corroborated by all we know of the power of this same condition in the lower animals. Generally, young women before commencing to breed are fat or at least plump. When they bear children they lose in weight by diminution of fat; again, as they cease to bear children, to resume the fat condition, the fat being now, however, differently disposed of in the body. The fat of the immature and of the post-mature is, within moderate limits, an indication of health. The fat of sterility is not an indication of health, but is, so far as I know, itself healthy, and indicates no active or positive disease. To obesity I only make allusion. I have known grossly fat women bear children; but facts about obesity are too few to justify its separation from the common exaggerated fatness of sterility here referred to.

Spencer makes a distinction between normal plethora and abnormal plethora as indicated by fat, and connects sterility only with the latter. I

quote his ingenious remarks not so much for the sake of giving his description of a distinction, the force of which I cannot see, as for the sake of stating his general argument regarding overfeeding or plethora as indicated by fatness. Medicine recognizes no normal plethora. For physicians plethora is always an abnormal condition whether accompanied by much deposit of fat or not. "Many facts," says Spencer, "may be brought to prove that fatness is not accompanied by fertility but by barrenness; and the inference drawn is that high feeding is unfavorable to genesis. . . . There is a distinction between what may be called normal plethora and an abnormal plethora, liable to be confounded with it. The one is a mark of constitutional wealth and this is the plethora which we have found to be associated with unusual fecundity. Abnormal plethora, which, as truly alleged, is accompanied by infecundity, is a superfluity of force evolving materials joined with either a positive or a relative deficiency of tissue-forming materials: the increased bulk indicating this state being really the bulk of so much inert or dead matter. Note, first, a few of the facts which show us that obesity implies physiological impoverishment. . . . Neither in brutes nor men does it ordinarily occur either in youth or in that early maturity during which the vigor is the greatest and the digestion the best; it does not habitually accompany the highest power of taking up nutritive materials. When fatness arises in the prime of life, whether from peculiarity of food or other circumstances, it is not the sign of an increased total vitality. . . . Of like meaning is the fact that women who have had several children, and animals after they have gone on bearing young for some time, frequently become fat and lose their fecundity as they do this. In such cases, the fatness is not to be taken as the cause of the infecundity; but the constitutional exhaustion which the previous production of offspring has left shows itself at once in the failing fecundity and the commencing fatness."

The fatness of sterility is not apparently a matter of high or of low general health, and seems to be of a different origin from that fatness which comes on men and women at the great climacteric, and on the latter whether they have borne children or not. Whatever may be its natural history it is known to be in some degree under the control of the physician. Not by medicine, but by diet and exercise, he can restrain its production or cause its removal. For success in removing fat the co-operation of the patient is necessary, for on her part there is required change of habits and restraint of appetite. Little can be said regarding the cure of sterility by reduction of fat, but experience has furnished no reason to doubt the favorable influence generally expected from it.

The regulation of desire and pleasure cannot be passed over without some remarks. Of the moral condition of those in whom these feelings are absent, or in whom they are in excess, I shall say nothing; and this silence is not because the moral condition is either unimportant or without influence on bodily health and on sterility, but because there is little that requires to be said. The healthy performance of the function of childbearing is surely connected with a well-regulated condition of desire and pleasure; and a well-regulated condition is not a reduction to a minimum or total absence, neither is it excess. I have already said that both desire and pleasure may be, and not rarely are, entirely absent; and it is my opinion, founded partly on the distinct testimony or concurrence of married women who are examples of the evil, that an education injudiciously ascetic, as it may be called, sometimes produces this de-

fiency, which is a source of much disappointment and disaster in married life; and this view is corroborated by what is quite certain—namely, that by indulgence the feelings may be, and not rarely are, produced or increased. Writing on sterility, Ambrose Paré gives directions how to increase desire with a view to conception. Equally important is excess of desire and pleasure, and its reduction within moderate limits is equally advantageous. Religion, morals, bodily health, and childbearing all combine to exalt the value and importance of moderation, and to show the evils of absence or of excess. The influence of separation of married people, or of living without cohabitation for a long time—a period, say, of several months—is very widely recognized; and it is probably dependent on the increase of desire and pleasure in those who have little of either, and on the restoration of them in those who have been rendered nearly impotent by excess. This power of separation has appeared to me to be far more frequently operative in women who have had a family than in those who are absolutely sterile; and remarkable cases are not rare.

I have heard and read of, but have not personally witnessed the disappearance of sterility after recovery from a fever; and this result is ascribed to the prolonged separation caused by the illness. The explanation may be correct, but it does not appear to be the natural one, for fevers are powerfully injurious to general health, and are known to disorder the ovarian and uterine functions.

I have already spoken of sterility as caused by marriage, especially in the young, and we know the sterility of prostitutes and the sterility of confined animals who couple freely or excessively, and it is probable that all these infertilities may have a bond of union in their being due to excessive desire and pleasure, or to excessive sexual indulgence, or to both combined.

In animals, especially in cows and mares, the semen is described as being not rarely expelled from the vagina soon after coitus; and this failure to retain is said to be, in some cases, owing to the animal not being duly in heat. Attempts are made to cause retention by dashing cold water over the buttocks and external parts. A like failure to retain the semen is frequently complained of by women, who describe it as coming away either immediately after coitus, and without leaving the horizontal position, or only on getting up. In either case women often attribute sterility to this failure of retention, and seek a cure of it with a view to fertility. Further, I have repeatedly been distinctly informed by careful women who habitually have this disagreeable imperfection, that conception has followed the rare occasions on which they have, as they noticed at the time, retained the semen. That this non-retention is often only partial is made probable by the occurrence of pregnancies in women who describe themselves as invariably suffering from it. It is rarely complained of except by the sterile, and I believe it is rare among the fertile. I have also a very strong impression, which I have no data to corroborate statistically, that it is especially common among those sterile women who have not sexual pleasure. I know nothing that modifies this condition, but believe that the production of sexual pleasure may have favorable influence. It probably depends on the failure of the timely dilatation of the cervix uteri, and perhaps of the uterine openings of the tubes so as to admit the semen, and on the failure of the simultaneous production of a condition of increased temporary negative abdominal pressure, or of that adspiratory action of the abdomen which numerous old and recent

authors invoke to explain the mechanism of fecundation; or it may depend on the failure of both of these conditions of ordinary successful coitus. Before leaving the subject I must add that the facts as to this profluvium seminis are not of the highest degree of security; for, so far at least as I am concerned, they are not more than the statements of intelligent wives. They are probably quite accurate, as they are certainly given in good faith; but it is possible that mucous discharges or glandular secretion through the ducts of Cowper or Duverney may be, in some cases, mistaken for semen.

The immoderately great consumption of alcoholic drinks by women, without their necessarily ever reaching the stage of drunkenness, is so common and so potent a cause of disorder and disease that it requires special mention. It is possible that much of the influence of this drinking might be justly ranked as part of mere overfeeding, whose injurious effects we have already spoken of, but this is far from certain. Indeed, while I am unable to give any strong evidence of the specially injurious action of alcohol, considered as an article of diet, I am much disposed to this view, being led to it by the good results in practice which I believe justly attributable to desisting from the use of it. The instances on which I rely are cases in which I have by physical examination and other modes of inquiry, been unable to discover any evidence of disease of the internal genital organs. It would not make the conclusion more assured to enumerate cases which are not in number or other circumstances sufficient for a demonstration. But I may mention the leading features of one which could not but strike the most careless observer. This patient was brought to me to be cured of sterility, and, as some prolonged treatment was expected, she proposed to reside near me for a time. She was between twenty and thirty years of age, and had been several years living in fruitless marriage, absolute sterility. On two occasions, with at least two years of interval, I declared my inability to do anything against the sterility by local means because I could discover no disorder or disease of the womb or its appendages. Having some suspicion of too liberal use of alcoholic drinks, I recommended teetotalism. After the lapse of a few years the patient, now a happy mother, was again brought to me on account of some trifling complaint, and I was told as follows: Her drinking habits having increased, she was induced to go into seclusion with rigid surveillance, and in this she lived for about a year without any kind of alcoholic drink. When she came home again she had lost much flesh, but was in good health, and she maintained what were now teetotal habits. She immediately became pregnant, and pregnancy recurred. Such cases are not singular, and induce a belief in a special hostility of alcoholic drinking to fertility.

But alcoholic drinking has, in addition to the general or constitutional disorder which it produces, well ascertained power, in certain cases, to induce disease of the internal genital organs. That which is most easily and distinctly made out is chronic ovaritis. It often comes and goes in the presence or absence of the cause. When it is present sterility is not always a result, but frequently so, and its cure is often followed by the disappearance of the sterility.

We have, lastly, to consider the power of various local and chiefly uterine diseases and disorders, which have too much engrossed the attention of the profession hitherto. As I have already remarked, there can be no rational doubt that these local affections have a very limited scope of action;

are, indeed, quite subordinate to the great causes of sterility affecting populations or classes. That they should have been the chief study of practitioners, as distinguished from statesmen or medical officers of health, is not only natural but in a sense just; for the practitioner cares not for the population or the class, but for the individual. If he is to do any good to the individual it is by discovering something amiss and providing a remedy that he must work. And where is a practitioner first to look for a special cause of sterility if not in the essential organs of generation? Here he finds several diseases, only in recent years the subject of scientific investigation, so-called ulcerations, displacements, strictures, subinvolution, and others, upon which he easily founds a theory, generally a mechanical one, of the sterility which he at once proceeds to attempt to cure. If he fails to cure that does not discourage him; for, in the present state of therapeutics, the reputation of remedies is founded more upon faith than upon evidence.

The wisest practitioner is he who, giving due weight to all items of knowledge acquired in regard to a disease or an unnatural condition, sets limits to his faith or his expectations, and scrutinizes the evidence on which a treatment is based, and this all the more severely if a certain result of the treatment is gain to himself.

Spasmodic dysmenorrhœa is the most striking morbid condition connected with sterility. It has its seat in the womb or its neighborhood, and it is by most gynecologists regarded as a purely local affection, having as its cause obstruction to the passage of the menstrual blood from the womb into the vagina by local or general congenital contraction of the canal of the cervix uteri. The nature of the affection and the place it occupies in the theory of sterility make me believe it to be a local affection in only a very limited sense—only in the same sense as irregular action of the heart or of the bronchi is a local affection. Its frequency, apart from numerous other considerations, is enough to make the pathologist hesitate to accept an alleged deformity of the cervix uteri as its cause. Besides, when the very rare alleged cause has really presented itself in rare cases of real pinpoint os uteri, dysmenorrhœa has not been always present; in my practice it has been always absent.

When evidence is led in favor of the obstruction theory of dysmenorrhœa the argument from the success of treatment by enlargement of the passage is generally held to be irresistible, and its force to be, if that is possible, increased by the cure of sterility which often accompanies the cure of the dysmenorrhœa, or, at least, follows the enlargement of the passage. The frequent success in curing or relieving dysmenorrhœa by this treatment, and the occasional success in curing sterility, are not matters of doubt. I have, indeed, no hesitation in saying that while many other pieces of advice are of great value in the treatment of the associated conditions of dysmenorrhœa and sterility, and in the treatment of them when not associated, this is the only medical interference that approaches in dignity to a cure. By this means, and chiefly by this alone, have cures such as concern us here been effected. In attestation of this utility we may cite the very great number of much vaunted means by which the object is effected, by very many kinds of knives, many dilators, many expanders, many scissors, by tents of various kinds, by bougies of various shapes, all of them, when put into use, producing enlargement of a part or of the whole of the passage through the cervix uteri.

For those who deny the existence of contraction it is not necessary to say a word further against the explanation of cure by mere enlargement. For

them that is certainly not the explanation. And it is easy to frame theories of the cure of dysmenorrhœa by enlargement of the passages, which may have the great superiority over that founded on obstruction, that they may also explain the cure of the associated sterility. Now, though the very simple cervical obstruction theory has been held sufficient to account for the sterility as well as for the dysmenorrhœa it is plainly in this respect impotent.

While it is doubtful whether any menstrual blood is regularly passed through the internal extremities of the tubes into the uterus, it may justly be held sufficient by the dysmenorrhœal obstruction theorists to consider the passage of menses through the cervix alone. But they, of course, extend their theory of causation and cure to sterility, and here it is semen whose passage has to be studied, not menstrual fluid, and the cervix is not the only narrowed part of the semen's route, for it must pass not only through the cervix, but also through the Fallopian tubes. And if the seminal obstruction theorists find impediments in the cervix with its comparatively considerable dimensions, such as to allow their knives or scissors to work, what will they say of the closed capillary channel of the internal extremity of a tube? Their cure of sterility merely enlarges a passage where there was no apparent mechanical obstruction, and leaves untouched a passage where there is apparent entire impermeability.

That the obstruction theory (in all except its absolutely certain applications, as in imperforate hymen—cases to which we here make no reference) is excessively exaggerated must be plain to everyone who regards the almost innumerable cases of fecundation in extraordinary circumstances—cases without penetration; cases of impregnation in peculiar conditions, through the rectum or through the urethra; cases in advanced uterine cancer; cases in procidentia with great cervical hypertrophy; cases in extreme distortion by fibroids; and others. In this matter the appeal to comparative anatomy is most instructive, and the argument from it very evident. The apparent mechanical difficulties in the way of the semen passing the cervix are, in some mammals, increased in an extreme and often a curious manner, without any consequent obstruction. To this matter Kehrér and Lott have paid particular attention, and have shown that the apparent mechanical difficulties affect the construction of the male organ in its relation to the female passage as well as the female passage itself.

To me it appears theoretically reasonable to connect the dysmenorrhœa and sterility with rigidity of the cervix, and the opinion that it is so is confirmed by its being actually discovered in most cases. Anyone familiar with the use of increasingly sized bougies in dilating the cervix must recognize the greater force required in dysmenorrhœal than in healthy women, and the increase of painfulness of the process as the force used, slight though it is, increases. The overcoming of this rigidity by temporary dilatation, not the overcoming of a mechanical obstruction, seems to me in some mysterious way to exert a generally beneficial influence on that part of the process of fecundation in which the uterus is implicated during insemination. For it may be held as almost certain that, during the natural sexual orgasm in coitus, the internal ends of the tubes, which we almost never see but as absolutely closed passages, are temporarily opened inside, and that the same happens to the cervix; and while it is probable that such wide opening of the cervix is not essential for fecundation, it must be held as facilitating it or rendering it more probable. Besides, this

opening is an indication that the whole nervous arrangements as well as the physical organs are co-operating to produce the object in view. The opening here pointed out has, in its natural or healthy performance, and in the obstacle from rigidity, close analogy with similar processes going on during the premonitory and first stages of labour; and the dysmenorrhoeal pains have analogy in the irregular painful and useless contractions and pains of these stages of labour, and of the hours immediately following delivery.

No other disease, local or presumably local, has such importance in the theory of sterility as spasmodic dysmenorrhoea. This great place is established by the frequent association of the two conditions, and by the probable connection of the dysmenorrhoeal neurosis with profuvium seminis, with disorder of sexual desire and pleasure, and with other derangements of the sexual orgasm of coitus. But dysmenorrhoea has its place confirmed in a unique way, for its cure is universally admitted to be a direct step towards the cure of sterility, and this can be said of no other local condition.

During recent times no disease has more engaged the attention of gynecologists than the catarrh and peculiar changes of the cervix uteri connected with it, known generally by the name of ulceration of the neck of the womb. To it, even when in a very slight form, has been ascribed a very great pathological importance, and the Croonian Lectures of West seem to have had less effect in bringing the profession to a just judgment of its comparative insignificance than the overshadowing influence of some other temporary novelty. Among other evils which this very prevalent disease has been alleged to produce is sterility; but there is not a tittle of evidence that it has any special influence in preventing conception; and we have, for guidance as to this matter, our best help in the fact that conception and natural pregnancy are extremely common during its continuance. Among twenty-six cases observed by Grünwaldt, with a view to the study of the changes of the cervix uteri in the first month of pregnancy, he found only eleven with a quite healthy state of the cervical mucous membrane. Six had papillary and nine catarrhal ulceration, which no doubt existed before conception.

Almost identical statements may be truly made regarding versions and flexions, and I do not repeat them. But in this department of gynecology increase of knowledge not only tends to diminish importance, but to show that the great mass of versions and flexions are conditions of simple health.

The importance of those diseases which prevent the commencement of uterine pregnancy, or render such commencement improbable or difficult, needs only to be mentioned. To Grünwaldt we owe a careful statement of the extent and potency of this class of diseases, and for them he, as already said, vindicates a morbid superiority over those conditions which prevent conception.

The diseases and disorders of the genital organs, whether they act in preventing conception, in preventing uterine pregnancy, or in interfering with its natural healthy progress, are operative in individual cases, and demand the most careful study of the practical physician, for it is chiefly through his power over them that he can hope to cure sterility. That in the early stages of the study of these diseases their influence should be exaggerated is natural. At all times there can be no doubt their study and treatment will be most important, not only on their own account, but with a view to the improvement of the general health. In the case of those local diseases which may be

proved to have no special influence in diminishing fertility, their removal, by increasing the general health, will help towards a removal of sterility.

Lectures

ON

PHTHISIS.

Delivered at Charing Cross Hospital,

By T. HENRY GREEN, M.D., F.R.C.P.,

Physician to the Hospital, Senior Assistant-Physician to the Hospital for Consumption and Diseases of the Chest, Brompton.

LECTURE IV.

Further consideration of the lung lesion.—Extent and distribution of the pulmonary consolidation.—Quiescence and activity of the phthisical process.—Physical signs indicative of quiescence and activity.—Symptoms indicative of quiescence and activity; pyrexia; digestion and assimilation; loss of weight; cough; expectoration; hæmoptysis.—Symptoms of phthisis.—Other elements of prognostic value; inherited predisposition; constitutional condition; age.

GENTLEMEN—In our consideration of the clinical varieties of phthisis we have seen the necessity of taking into account both the lung lesion and the symptoms which accompany it. Last time we were occupied in discussing the lung lesion with reference to: (1) Its characters and the secondary changes it underwent. We have now to consider it with reference to: (2) Its extent and distribution; and (3) its quiescent or progressive nature.

2. *The Extent and Distribution of the Pulmonary Consolidation.*—It is necessary to consider both the extent of lung involved and the distribution of the consolidation. With regard to the former it is only needful to say that, *quoad* area of lung implicated, the more limited this is the better the prognosis. The distribution of the consolidation is also an element of much prognostic import. Speaking generally, it may be said that a massed is more favorable than a disseminated distribution of the lesion. The phthisical process at its commencement is usually confined to a single portion of the upper part of one lung. Physical signs, therefore, which indicate the existence of separate centres of consolidation in the same, or the implication of the opposite, lung, imply, for the most part, that the disease is progressing. This progressive tendency we are about to consider.

3. *The Quiescent or Progressive Nature of the Consolidation.*—The great characteristic of phthisical consolidation, as you will remember from our previous pathological considerations, is its tendency to spread, either by continuity or by the dissemination of the inflammatory products by vessels or bronchi, so that distant portions of the lung become involved. This infective property, although it varies in degree very considerably in different cases and under different circumstances, probably exists in all phthisical lesions, except in those old indurations which have become exclusively fibroid. Given therefore the existence of phthisis, even if the local process is not progressive at the time of observation, we anticipate the probability that it may sooner or later become so. The question, therefore, we have to consider is what signs and symptoms are indicative of the quiescence and activity of the lung lesion respectively. Our opin-

ion on this head will be based upon a consideration of the results of physical examination of the chest and also of the symptoms of the disease.

Firstly, with regard to physical signs. Here I must ask you to bear in mind what we stated in the preceding lecture respecting the predominating characters of the pulmonary lesion, their physical diagnosis and clinical import. Remember the distinction between consolidations which consist almost exclusively of intra-alveolar products and those in which there is marked implication of the walls of the alveoli with increase of interlobular connective tissue; and note that the former only are capable of complete resolution. The physical signs which in a case of intra-alveolar consolidation are of favorable import are, as we have already stated, the gradual disappearance of the dry and moist crepitant râles, with diminution in the percussion dullness and in the deficiency of the respiration; those which indicate progress of the disease are the persistence of the crepitant râles and dullness, with, owing to the implication of the alveolar walls, the supervention of some shrinking of the lung. Speaking generally, it may be said that in all cases crepitant sounds are significant of activity of the disease. When softening of a consolidation is taking place, as indicated by the existence of the so-called moist crackling, it must be borne in mind that there is always a danger that the phthisical progress will involve adjacent or distant portions of the lung. With the completion of the softening process we carefully consider the cavity which is its outcome. The subject of cavity is so important that I propose to speak of it somewhat fully on a subsequent occasion. In its present connection I would only remark that the most valuable information respecting its quiescent or progressive nature is to be derived from an examination of the immediately adjacent portions of the lung. The absence here of any crepitant râles or of other signs of progressive consolidation is favorable as indicating a tendency to fibroid limitation of the excavation. In the cavity itself the absence of moist râles with the existence of dry crackling sounds point to quiescence and tendency to contract.

All signs indicating spreading of the disease, whether by continuity or otherwise, are obviously of unfavorable import. This is, perhaps, especially the case where outlying portions of the lung become involved. Stethoscopic investigation beyond the area of primary disease is consequently of the utmost importance, and crepitation or other adventitious sounds here are carefully to be looked for. Lastly, signs of bronchial catarrh in portions of the lung not obviously consolidated, are always to be regarded with suspicion, inasmuch as such catarrh is frequently, but by no means invariably, accompanied by activity of the disease. Here, however, as in other points, we shall be guided largely by symptoms.

Symptoms are even more valuable than physical signs as evidence of the quiescence or activity of the phthisical process. Of these pyrexia is pre-eminently the most important, and its existence in the course of phthisis, in the absence of other causes, must be regarded as a certain sign of the activity of the disease. You will remember the two causes of fever in phthisis—the progressive implication of the lung, and the softening of the phthisical consolidation; and that the pyrexia due to the latter is much more remittent in its type than is that due to the former. A continued though more or less irregular fever is most characteristic of progressive consolidation and this is, therefore, of much graver import than is the purely remittent type which is met with principally during the softening of the more acute and localized lesions.

Inasmuch, however, as consolidation and softening are so frequently associated, the pyrexia is most commonly the combined result of the two processes. These three charts well represent the differences of which I am speaking. You will not forget the frequency with which the febrile movement occurs in the early part of the afternoon, and subsides before eight or nine o'clock, the usual time for taking the evening temperature. Hence the importance of including the afternoon in our observations. The entire absence of fever certainly indicates the quiescence, though not necessarily, the complete inactivity, of the phthisical process.

Of other general symptoms, the processes of digestion and assimilation, the weight, and the pulse are also of value, as indications of the progress or the arrest of the disease. For the most part, however, they are so indirectly. Whatever impairs the general health favors the phthisical process, and whatever improves it tends to cause its arrest. Hence failure of digestion and assimilation is always of unfavorable import, and even if not at the time associated with activity of the disease, it is very likely soon to become so. Loss of weight has a similar significance. With regard to the pulse, it is only necessary to say that continued increase in its frequency, as being the result of a febrile process or of general weakness, points to progress.

The lung symptoms which are of value in this connection are cough, expectoration, and hæmoptysis. The gradual disappearance of cough, except in the latest stages of the disease when the respiratory function is in abeyance, is obviously of favorable significance; but a continuance and even increase of this symptom is not necessarily of bad omen. Arrest of the phthisical process, with diminution of the catarrhal secretion, and a tendency to slight fibrosis and contraction, is very frequently attended by increase of cough, which, owing to the absence of secretion, becomes more troublesome to the patient. This fact it is important to remember.

The significance of the sputa in phthisis varies according as it originates mainly in the bronchi, in softening consolidation, or in cavities. In cases of chronic phthisis with more or less bronchial dilatation, and also in cases of excavation, the expectoration of large quantities of muco-purulent material indicates a persistence of the catarrhal process, which if long continued is likely to lead to an increase in the pulmonary induration. In early phthisis also the sputa originate principally in the bronchi, and much expectoration usually indicates activity of the disease. During the process of softening the amount of expectoration varies according to whether or not there is a free communication between the softening masses and large bronchi. It may, therefore, be stated generally with regard to the expectoration in phthisis that diminution in amount is of favorable import, while the persistence of large quantities of sputa is indicative of more or less activity of the phthisical process.

Of hæmoptysis we shall have to speak on a future occasion. I would, however, remind you here that the prognostic value of this symptom is not the same in recent as in old lesions. In the former, the bleeding is usually capillary in its origin and its occurrence is usually associated with a certain amount of activity of the disease, the degree of which, as we shall see, is to be estimated by the thermometer. In old lesions, on the other hand, the blood more frequently originates from a small artery in a cavity, and although the immediate danger from the hæmoptysis is greater, there is, owing to the induration around, much less

liability to the progressive implication of the lung.

This completes our consideration of the lung lesion. Of that other factor, the symptoms which accompany the disease, but little remains to be said, inasmuch as most of these have been already alluded to when speaking of the quiescence or activity of the phthisical process. You will, however, remember that symptoms are of the utmost importance; some of them, and especially those we have termed constitutional as distinct from lung symptoms, being in most cases of greater value than physical signs as evidence of the course of the disease. Pyrexia and marked impairment of digestion and assimilation are always unfavorable, and whilst they last are pretty sure indications of progress.

There remain three other circumstances which should always be taken into account in forming an opinion as to the probable course of phthisis: hereditary predisposition, constitutional state, and the age of the patient. The unfavorable influence of heredity is so marked and so universally recognized that its consideration need not now detain us. The offspring of phthisical parents inherit a constitutional feebleness which not only renders them abnormally liable to become phthisical, but probably also in many cases, abnormally incapable of resisting injurious influences of other kinds, and thus their period of life tends to be shortened. This inherited weakness not infrequently impresses upon the individual physical peculiarities which enable us easily to recognize it—the small thorax, long eye-lashes, and back covered with long downy hairs, with which you are all familiar. In those in whom inherited tendency is thus marked the course of phthisis is especially unfavorable.

The constitutional condition most favorable to the development of phthisis is, as you are aware, that inherited one to which we have just alluded. But in addition to this transmitted influence other conditions of constitution may be inherited or acquired which render the individual abnormally prone to become phthisical. It may be stated generally that all conditions of constitutional enfeeblement, whether due to impaired vitality of the parents, or the result of unfavorable hygienic surroundings or of disease after birth, favor the development and the progress of phthisis, and the existence of such constitutional weakness should not be lost sight of in making a prognosis.

With regard to age, early adult life is undoubtedly the period most favorable to phthisis. In middle and advanced life the disease is less prone to occur, and its course is usually more protracted.

My own experience in the treatment of affections of the eye has given me, I have thought that I might with most advantage take up those forms of ophthalmic disease that are of the most frequent occurrence, those which the members of this Society are certain to meet with in the pursuit of their profession, and the treatment of which they are in many instances compelled to undertake. I have sometimes regretted to hear practitioners say they know nothing of diseases of the eye, and that they regard it as a special subject which is too vast in extent to allow them even to attempt to learn. I hold rather that every surgeon and physician should be familiar with ophthalmic disease, though it may not be given to each to become a skilful operator. There are many affections which every practitioner may be called upon to treat, and upon whose knowledge the patient would confidently rely, though few might be willing to submit themselves for the operations of cataract, artificial pupil, or squint to any but those who are accustomed to this work, because it is well known to the laity that such proceedings require constant practice, proper instruments, and experience in the after-treatment.

The formation of special departments in all our hospitals for the investigation and treatment of particular forms of disease has its advantages and disadvantages. On the one hand, by collecting in one place and at the same time a large number of patients suffering from disease of the same organ, excellent opportunities are afforded for studying their relations, for classifying them into groups, for recognizing minute distinctions, and of following their course and observing the effects of treatment. It is, moreover, of great importance to the teacher, by enabling him to make his lectures clinical, and to demonstrate upon the living subject the points on which he dwells in the classroom. It is of still greater value to the student, by facilitating his work and affording him, if he is intelligent and attentive, the opportunity of seeing many examples of the diseases of each organ in a very short space of time. Lastly, it is of the greatest value to the patient, by giving him the services of skilled and highly trained men, at whose disposal are all the appliances that experience can suggest. These are undoubted advantages. On the other hand, there are some disadvantages in the system. By withdrawing all or nearly all the patients suffering from the diseases of a particular organ from the general wards, it becomes imperative that the student should attend in the special wards, or he is likely to leave the hospital entirely ignorant of a whole class of diseases. But as a matter of fact the requirements of modern examinations are such that the student can hardly spare any time from that which he must devote to the pursuit of general medicine and surgery, in order to follow particular branches. He may perhaps once or twice in the course of his last year present himself in the special wards, but he finds himself almost in another atmosphere. Not only the diseases, but their very names, are new to him. He quickly perceives that some considerable time and a succession of visits must be paid to prove of service, and he either thinks he will postpone his labors in this direction to a more convenient season, when he forgets to return, or which perhaps never comes, or he comforts himself by reflecting that even if he is perfectly ignorant of the diseases of the eye he may still manage to struggle through his examination, providing he can escape the single written question on such subject which it is just to say is often given in his paper, whilst if the exigencies of his future practice ever cross his mind, he comforts himself with the reflection that in the event of his being

Lectures

ON

AFFECTIONS OF THE EYE IN RELATION TO MEDICINE AND SURGERY.

Delivered at the Harveian Society.

By HENRY POWER, M.B. Lond., F.R.C.S. Eng.,

Senior Ophthalmic Surgeon and Lecturer on Ophthalmic Surgery, St. Bartholomew's Hospital.

LECTURE I.

GENTLEMEN—In considering how I could best fulfil the intentions with which this series of lectures was instituted by the founders, and render serviceable such knowledge as a somewhat length-

called upon to treat a difficult case he will always be able to obtain a special opinion, or if the worst comes, and an eye is lost, nature has given us two, and a man can see nearly as well with one as with both. I need hardly say how suddenly a change comes over him with the first serious case that occurs in practice. It may be of iritis or of glaucoma. Then the possibilities of blindness in his patient force themselves upon him, resulting, he cannot but feel, from his own ignorance. The professors of obstetric medicine and surgery are in some of these respects placed at an advantage to the ophthalmic surgeon. In the first place, gynaecology forms a very important and, indeed, essential part of the medical curriculum. The student is well aware that he will be strictly examined upon it. He has to obtain special certificates showing that he has attended so many lectures and so many cases, and he has had it well drummed into him, if his father happen to be a practitioner, that a knowledge of it is absolutely necessary in country practice, and will always prove serviceable to him whether he practice at home or abroad, whilst he knows that it is not at all unlikely he may be called upon to treat a difficult case upon his own responsibility at an early period of his career, and under circumstances in which his proceedings are sure to be sharply criticised.

In making these observations I trust I may not be regarded as in any way discrediting the knowledge of diseases of the eye possessed by a large and steadily increasing number of practitioners, nor of under-estimating their zeal and attention in the study of these affections. Many men now leave our hospitals with a very sound practical knowledge of this class of affections, and in after-life obtain the opinion and assistance of a specialist only when an operation is required, or to obtain his support to a line of treatment they have themselves inaugurated, and as a safeguard against subsequent mishap. There can be no doubt, however, that what is done by the few more intelligent students should be rendered imperative on all, and that the time at the disposal of the student should include another year to enable him to pursue the study of medicine and surgery in the special departments of the eye, ear, larynx, and skin, and that the attendance upon lectures and in the wards, and the attainment of some knowledge in these subjects, should be rendered compulsory. That space of time would be sufficient to familiarize the student with the principal forms of disease and with the use of the instruments employed in the diagnosis and treatment of each class of affection, such as the ophthalmoscope, laryngoscope, Eustachian catheter, and the like; and the student would thus be better prepared for the battle of life, and cases of iritis, in which adhesions have been allowed to occur which might have been prevented, and cases of glaucoma which have been allowed to progress till the patient is blind, and beyond the resources of surgery, happily even now rare, would be altogether unknown.

The most painstaking student, however, after the lapse of a few years is apt to become a little rusty in departments which do not often fall under his notice, and things that were once very familiar are quite forgotten. This is especially the case with the use of the ophthalmoscope, which not only takes some time to learn, but is soon lost, for few cases fall to the lot of the young practitioner to enable him to keep up his knowledge, and after the lapse of some years he hesitates to rely on his own judgment to decide whether the margins of the optic disc are in a given case really blurred and indistinct, or whether the media are cloudy, or whether it is only an error of refraction, or what degree of whiteness of the optic nerve has passed

beyond physiological limits. I am therefore somewhat doubtful whether the ophthalmoscope will ever be widely used by the general surgeon; and I have thought, remembering the practical character of our meetings, that it would prove acceptable to the members of the Society, if instead of attempting to give a description of exceptional forms of internal disease of the eye, I were to discuss some of those affections which are of every-day occurrence, and to place before you such information as modern research has obtained upon diseases that every practitioner may be called upon to treat, or which his advice may prevent. I propose then to take as the subjects of these lectures purulent ophthalmia, keratitis, and myopia.

Before commencing the subject of purulent ophthalmia, perhaps I may be allowed briefly to describe the anatomy and histological characters of the conjunctiva, which will enable me to explain more intelligibly the changes that occur in disease. It is, as is well known, a mucous membrane which lines the lids, and is continuous with the skin at their margin anteriorly, whilst posteriorly it is reflected upon the globe. It is thus divisible into a tarsal and an ocular or bulbar portion, which are connected by a fold, termed the conjunctival fold, or retrotarsal portion of the membrane. The tarsal portion is composed of mucous membrane directly and firmly applied to the tarsal cartilage, with little or no submucous connective tissue. This part is highly vascular, and presents numerous small, low, conical papillae near the free edge, which become broader and more prominent near the sinus. The deeper epithelial cells are columnar, the more superficial tessellated. Distributed amongst them are many goblet cells. The ocular portion of the membrane is destitute of papillae, and presents flattened epithelium. The submucous tissue contains much elastic tissue in the fold, and is therefore very extensible, and as in the scleral portion, contains a few small collections of fat cells. The conjunctiva and the sclerotic are very closely united near the border of the cornea, but rather loosely elsewhere. The vessels are divisible into two sets, the superficial and the deep. The superficial arteries are derived in part from the ophthalmic muscular branches, and in part from the anterior ciliary arteries; the deep, or episcleral arteries spring from the muscular and from the palpebral arteries, and are comparatively few. The superficial veins are few in number, and communicate at the periphery of the cornea with the canal of Schlemm. The deep veins are numerous, and end in the muscular veins. The nerves are derived from the ophthalmic division of the fifth pair; they present many terminal bulbs. The glands of the conjunctiva are the acinous glands, or glands of Krause, sometimes also called accessory lacrymal glands. These are particularly found in the upper fold of the conjunctiva, arranged transversely from the inner extremity of the lacrymal gland towards the inner part of the eyelid, in which direction they increase in size. Usually there are from twelve to eighteen, though Krause in one instance counted forty-two. In the fold of the lower lid there are only from two to six. The excretory duct is thin-walled, and perforates the conjunctiva obliquely. Besides these there are certain spherical or completely closed follicles, which very closely resemble the solitary glands of the intestine, and lie immediately beneath the surface of the membrane. They possess an investing membrane, and are traversed by a plexus of connective tissue, in the meshes of which are numerous leucocytes, resembling or identical with lymph-corpuscles. Loops of blood-vessels appear in their interior on section. Their diameter is about 0.4 mm., or

about one-fiftieth of an inch, and they are chiefly found in the fornix according to Krause, though Waldeyer denies their existence, and thinks that, if there be any in man, they are only to be found scattered here and there. In the ox they form masses known as the "plaques de Bresch," which are sometimes regarded as normal and sometimes as abnormal textures. The lymphatics of the conjunctiva bulbi are very numerous, but they are more sparingly present in the other portions of the membrane. At the margin of the cornea they form a delicate close-meshed plexus of very fine vessels with dilatations at the points of junction. The plexus terminates towards the cornea in a series of flat arches, and this ring of vessels, having a breadth of about one millimetre, is named the *circulus lymphaticus*; sometimes a single large vessel forms the boundary of the plexus and surrounds the cornea in a somewhat interrupted circular form. This is connected with a number of radially arranged vessels proceeding from the cornea itself, whilst other vessels proceed to the lids, and, running laterally inwards or outwards, open into vessels provided with valves, which again enter the superficial facial lymphatic glands and the sub-maxillary glands. The lymphatics everywhere occupy a position subjacent to the bloodvessels.

Having thus epitomized the chief facts in the histology of the conjunctiva, I may now pass on to consider that form of disease which is termed purulent ophthalmia, and especially that form of it which is apt to occur in the new-born child, the well-known ophthalmia neonatorum. Estimates have been given by different authors of the number of cases of blindness referable to this cause that are found in blind asylums. By one writer it is placed as high as 70 per cent. The tables of Cohn, however, which are of recent date, seem to show that diseases of the conjunctiva, though constituting nearly one-half of all the diseases of the eye, yet in the form of the purulent ophthalmia of infants is the cause of only 33 per cent. of all cases of blindness, whether in or out of asylums, occurring between the ages of five and twenty years. At every ophthalmic hospital cases continue to present themselves which are evidently suffering from the consequences of this disease. In the worst cases the eye is atrophied and squared by the action of the recti muscles or reduced to a button; in others the cornea is perfectly opaque or is replaced by cicatricial tissue, proving that it has formerly been violently inflamed, and has sloughed. In others, again, the whole globe is enlarged, showing that the inflammation has softened the tissue of the sclerotic and cornea, and that they have yielded to the steady pressure of the contents of the globe, so that the eye bulges between the lids; whilst in the less severe cases a white spot, or leucoma, to the inner surface of which the iris is often adherent, indicates the former presence of a penetrating ulcer. In almost all of these latter cases the vision is greatly impaired, the pupil being displaced, and the capsule of the lens being often the seat of a deposit of lymph. Of course many of these cases have been under the care of midwives, or under no care at all; others are incurable from the moment they are first seen, resisting all remedial means; but in some I am disposed to think better results might have been obtained if the serious nature of the affection had been earlier recognized, and if the surgeon, instead of giving verbal directions to perhaps a careless or ignorant nurse, had himself taken the trouble to attend to the infant. It is in the early stages of the complaint that most advantage can be obtained from treatment; and on the principle that example is better than precept, the benefit obtained by the surgeon himself showing

how the remedies should be applied, is far better than any instructions, however clear and precise they may be.

The general characters of the disease must be familiar to all my hearers, and I do not intend to enter very minutely into the symptoms. In the majority of cases the presence of yellow secretion first attracts notice, and the disease is said to commence upon the third day after birth; but it sometimes begins a little earlier, or is retarded to the fifth, sixth, or seventh day, or even somewhat later. The secretion rapidly increases; the conjunctiva, both of the lids and of the globe, becomes red and chemosed. The lids swell and assume a red or livid tint. The pain seems to be inconsiderable, or, at least, considering the violence of the inflammation, is not a characteristic feature of the disease, perhaps because the tissues are so loose that swelling is readily effected and there is little or no pressure on the nerves. The secretion, at first thin and yellowish, soon becomes thicker, with flocculi of puro-mucous material floating in it, and then of a full yellow color, the very type of the pus laudable of the older writers. On wiping it away, the surface of the lid often presents a kind of thin membrane which can be picked off with forceps, sometimes leaving only a reddened surface beneath it, but sometimes a bleeding surface, and then tending to the diphtheritic form. Hæmorrhage from the over-charged vessels sometimes occurs spontaneously, and frequently occurs on merely raising the lids. The eyes, owing to the swelling of the lids, are constantly kept in the closed condition, and the child is unable to raise them by the action of the levator palpebræ. Moreover, as the edges of the lids adhere in consequence of the drying up of the secretion during sleep, the pus accumulates behind them and bulges them out to a remarkable extent. After remaining for some time in this condition of acute inflammation, the disease, sometimes spontaneously, or with the aid only of simple remedies, begins to subside and passes into a chronic state, in which the conjunctiva remains villous and granular, with swollen papillæ, ready on slight provocation to suffer a relapse, but slowly tending to recovery. In a large number of cases, however, the nutrition of the cornea is interfered with by the obstruction to the capillary circulation in the ciliary region, and sooner or later it presents a partial or general haziness. When the cloud is partial, it is often situated near the periphery of the cornea, and close inspection will then show that at this point, and more or less concealed by the chemosed conjunctiva, there is an ulcer or sharply defined groove. When this has once formed the chances are greatly in favor of its becoming progressively deeper, and at length perforating; the aqueous then escapes, and the iris becomes applied to the inner surface of the opening. For a day or two no apparent harm is done, but soon a little black speck appears at the site of the ulcer, which is the delicate tissue of the iris thrust forward by the pressure of the aqueous accumulating behind it, and covered by the membrane of Descemet. It continues to increase till it becomes nearly as large as the head of a fusée, producing a considerable amount of irritation and lachrymation. The protrusion may either remain, becoming invested with cicatricial tissue, or it may gradually flatten down and become nearly level with the rest of the cornea, leaving only a displaced pupil. Various opinions have been held as to whether the corneal lesions are due to the character and quality of the pus or to the degree of chemosis. It is certain that the mere contact of pus with the cornea is productive of but little harm. In cases of suppuration of the lacrymal sac pus is often poured into the conjunc-

tival sac by regurgitation through the canaliculi, or through an artificial opening, for a considerable period without occasioning infiltration or ulceration of the tissue of the cornea, which remains bright and polished. The early period at which lesion of the cornea occurs, as well as the received views on the etiology of the disease, have led many to suspect that the pus may contain some virus capable of directly eroding its tissue. But it is obvious that a powerful disturbing influence must be exerted on the cornea by the chemotic infiltration of the conjunctiva, since, when this is strongly expressed, as it is in most cases of purulent ophthalmia, the vessels of the ciliary region must be compressed, the venous circulation retarded, and the conditions favorable to diapedesis or emigration of white corpuscles from the vessels induced. The importance of such compression is particularly well shown in cases of diphtheritic conjunctivitis, happily almost unknown in this country, though familiar enough to practitioners in Germany.

Arlt has justly observed that in the event of much chemosis and conjunctival infiltration occurring at the end of the second week, it is impossible ("Annal. d'Oc." 1880, p. 182) in all instances to preserve the cornea from becoming the seat of an abscess, and virulent blennorrhœa may be held to have been present.

If the cornea becomes generally hazy, the prospect is very discouraging. The haziness gradually deepens into opacity; the cornea becomes softened; pus forms between the lamellæ; it yields at some part of the periphery, or gives way altogether. The lens escapes, and the eye collapses, no vestige of vision remaining. In such cases mothers sometimes bring the lenses in a pill-box or wrapped in paper, saying that these had escaped from the eye, and half expecting apparently that they may be replaced.

(To be continued.)

Original Papers.

TWO CASES OF ENTERIC FEVER: A CONTRAST.

By JAMES FERGUSON, M.B.

THE following two cases when placed together form a useful contrast, and it will best serve practical purposes if we consider first their clinical aspects and then the post-mortem reports.

The first is that of J. P., aged nineteen, a sailor, admitted into the Perth Infirmary on August 29th. After a stormy passage from London, the lad had great difficulty in reaching the hospital on foot. The temperature on admission was 105° F.; pulse 120. Local signs: well-marked tenderness in the right iliac fossa and a slight general distension of the abdomen; there were but two characteristic spots. During the next eight days the temperature ranged from 100.6° to 105.8° F., reaching the former record only after liberal antipyretic treatment; the pulse was quick and feeble; nervous symptoms particularly prominent; the pupils dilated, and the face flushed and anxious. The tongue became brown, dry, and hard; the iliac tenderness soon spread, and frequent abdominal pain was noticed, though there was but little tympanites. Notwithstanding prompt treatment, diarrhœa persisted, the number of stools varying from four to ten per diem; latterly these were characteristic, but blood was only thrice noticed,

and then in small amount. Death from syncope occurred on the ninth day.

The case illustrates the crossing of two of Murchison's types, the irritative and the abdominal, both of which are grave. Remembering the hard usage which the youth received in the early and acute stage of the attack, we need not wonder at any aggravation of the symptoms or at the results. Possibly to the same cause, and more especially the rough medical treatment of the shipmaster, was due the extreme degree of tissue destruction to which the state of the intestine bore witness.

The second case, J. M., aged twenty-one, a domestic servant, was admitted on the 14th of October. The illness had begun with a week of malaise, headache, and obstinate constipation. On admission her temperature was 102.2° (8 P.M.), pulse 98; slight distension of abdomen, but neither pain nor tenderness. Mental and bodily inaptitude was marked, and persisted until the ninth day, after which nightly delirium and restlessness set in. Till the twelfth day the bowels remained constipated, but for two days after this there was slight diarrhœa. The temperature was generally somewhat high, though 104.4° F. was the maximum. On the seventh day an erythematous eruption was found on the chest, arms, and legs; but this faded away in two days, again appeared, and in two more days went entirely. The true rose-colored spots were never found, but a few of a deeper tint showed themselves in successive crops. A frequent loose cough with moist râles occurred, and the weakness of the patient rendered expectoration difficult. Coincident with these changes were increased frequency and weakness of the pulse, which reached from 120 to 128 in the morning, and once to 140 at 6 P.M. About 3 P.M. on the seventeenth day in bed, a suddenly increased pallor attracted attention, when the patient was found to be lying in a pool of blood, very dark and fluid, and with no admixture of solid matter. The patient was unconscious of her condition, though making faint response to questions. The pulse was almost imperceptible. A lead and opium pill was given, with an injection of iced water into the bowel, five grains of ergotine subcutaneously, and an iced bag applied over the abdomen. The patient rallied slightly, but at 2 A.M. a less copious hæmorrhage occurred, and she collapsed in half an hour more.

The remarkable absence of the classical signs in this case is noteworthy. Almost throughout the high temperature was the only striking symptom, but the obstinate constipation is not in my experience at all so rare as is usually stated. Jenner has noted a case in which the bowels were inactive all through, and in which death ensued, as in this, from hæmorrhage. He sets down as the most common cause of costiveness deep ulceration, and cautions against a ready recourse to laxatives. The absence of the typical eruption and the occurrence of an erythematous rash followed by darker spots are interesting in view of Murchison's observation, "Now and then the appearance of the lenticular spots is preceded for two or three days by a delicate scarlet rash all over the body. I have noted this rash in five out of forty-five patients admitted into hospital within the first eight days of the disease." This is the only case in which I have observed such appearances among seventy treated in this infirmary. Murchison's only detailed case was marked by prolonged constipation. The proverbial variety of forms assumed by this disease will be noted in these two cases, and more especially as regards the condition of the nervous system, the temperature, the abdominal symptoms, and, most impressive of all,

the contradistinction in the modes of death. In the first we had evidence of extreme destruction of tissue, and yet death was not immediately traceable to that cause; while in the other there were almost no signs whatever of local interference, yet breach of tissue of a most definable kind was the cause of death.

We have now to examine the portions of the intestines presenting the characteristic changes, with the mesentery and its glands from each case. On the peritoneal aspect of the intestine from the first case, about four feet from the upper end of the small bowel, spots of congestion began to occur, at first small, circular, and of pinkish hue, but as they passed downwards becoming larger, more longitudinal and livid, until they ended in patches with a yellow centre, surrounded by zones of deep congestion. Stripping off the peritoneal coat of the bowel revealed that localized spots of vascularity in that membrane accounted largely for these appearances. We now found towards the lower end of the ileum that a jet of water burst out in the process. This escape took place from three minute orifices, and corresponding with these was a congested state of the peritoneum, so that there was a perforation of the bowel, except in its outer coat. On opening the bowel, the glands were found to be deeply implicated, and with the exception of cicatrization, there were perhaps none of the characteristic changes unrepresented. There was a terrible amount of destruction, beginning in the solitary glands, about four feet from the pylorus, and as regards Peyer's patches, these were represented by spots of disease varying from half an inch to three inches in length, and also by two still larger areas of ulceration lying in the last nine inches of the bowel. Among thirty-one different spaces, the various stages of change were presented, and in the last ulcer of the series perforation had threatened as above described. This ulcer encircled the whole of the tube, and passed upwards on the ilio-cæcal valve, as far as its margin, involving the whole of its iliac, but leaving the cæcal aspect of the valve free from disease. Passing downwards, now in the large bowel, the vermiform appendix was found highly congested externally, while inside it was crammed with yellowish-green curdy matter. Over the cæcum, along the whole of the ascending, and about half way on the transverse colon, at first in great abundance, and gradually decreasing in number, were well-formed ulcers, closely resembling the diseased solitary glands of the upper bowel. The implication of the large bowel was exceptional, and very severe. The enlargement of the mesenteric glands was also extreme, some of these being twice or thrice the size of a pigeon's egg.

The post-mortem appearances in our second case contrast strongly with those above described. The changes in the small bowel were confined to the last three feet of its length, and were characterized by large and deep sloughs. It is noteworthy that this has been remarked as a feature of cases distinguished by prolonged constipation. Only four of the Peyerian patches were involved; but it may be mentioned that a limited amount of ulceration existed in the large bowel, which would indicate its implication in cases not necessarily of great severity in the upper track. The large bowel presented an appearance of red staining rather than of hyperæmia, and contrasted with the blanched hue of the duodenum, while this last state was also the opposite of that found in the first case. To complete the contrast, the mesenteric glands were here but slightly affected.

Perth.

REMOVAL OF THE BREAST, FOLLOWED BY SPONTANEOUS FRACTURE OF THE FEMUR.

UNION OF THE SAME, WITH FRACTURE AGAIN FOUR WEEKS AFTERWARDS BY A BONE-SETTER IN ATTEMPTING TO REDUCE A SO-CALLED DISLOCATION OF THE HIP-JOINT.

By JOHN HAMILTON, F.R.C.S. Ed.

THE notes of the following case may be considered somewhat interesting.

The patient, M. O—, aged fifty-six, enjoyed good health, with the exception of an occasional passage of nephritic calculi. She first noticed a slight lump at the inner side of the right nipple, about sixteen months since, which quickly increased until it attained the size of a small orange, attended at times with acute pain. On examination there was found to be no retraction of the nipple, and but slight adhesion of the skin over the tumour, which was of bony hardness, and freely movable on the parts underneath. There was slight enlargement of one or two axillary glands.

In consultation with Mr. Clements, of Burton, and Mr. Moon, I determined, with their approbation, to remove the breast, which I did completely under chloroform. The incision was necessarily a very extensive one, because of the largeness of the mamma and the necessity of removing the axillary glands. On its removal it was at once seen to be a well-marked case of *cirrhosis*. The wound was treated by simple sutures, supported by adhesive plaster strappings, and over all a well-adjusted pad of dry lint. The sutures were removed on the third day, and by the eighth it was entirely healed, without seeing throughout the slightest trace of pus. About three months afterwards the patient in crossing the floor of her bedroom felt something give way in her right thigh and suddenly fell to the ground. Being from home myself at the time, she was seen by Mr. Moon, of Gresley, who at once diagnosed fracture of the femur, and took the necessary steps to put it in a favorable position for union. On returning from my holidays a few days after the accident, I examined the thigh and satisfied myself as to there being a fracture. I explained to the patient's relatives the absolute necessity of rest, and in reply to their query told them how long I thought it would be necessary to keep her in splints. On visiting the patient again about a fortnight after, I was surprised to see the apparatus I had constructed for extension placed in one corner of the kitchen, and upon inquiring as to the meaning of its being there, I was informed by her husband—who has since died—that "it was all right." Not waiting for any further explanation I hurried upstairs, wondering to myself how it had got "all right" so soon. Upon inquiry of the patient, she said that she "was sorry I had made a mistake; a bone doctor had been over and found that her hip was out, and, as the patient admitted, took very strong measures for its reduction, one of which was to pull her out of bed. On leaving he assured her that she would be able to get about in a very short time—less than a week. My first impulse was to leave the house at once, but my curiosity got the better of my resolve. I examined the limb, and found, as I expected, the splints removed, the leg shortened by fully four inches, and the slightest manipulation causing intense pain. I now pointed out to the patient and her relatives the harm that had been done, and for the first time informed her (which for obvious reasons I did not

wish to do before) that the easy breaking of the bone was in some cases an occasional corollary of cancer, and to prove still further the uselessness of the bone-setter's procedure, left without doing anything to put the limb in position.

A few days after, at the earnest entreaty of her friends, I again visited her, and found that a very great revulsion of feeling had taken place. The former gratefulness to the "bone-doctor" had now given way to a strong feeling of resentment, and an action for damages was loudly spoken of, ending, however, in talk, the game being considered not worth the candle. I now endeavored to get the thigh once more into position, which I need not say without chloroform (the patient absolutely refusing to have any) was almost impossible, readjusted the splints, and at the expiration of three months there was again firm union. But I am sorry to say there is so much shortening as to almost make the limb an encumbrance rather than a help.

Swadlincote, Burton-on-Trent.

THE ANASTOMOSIS OF THE CORONARY ARTERIES.

By SAMUEL WEST, M.D.,

Physician to the Chest Hospital, Victoria-Park.

THE anastomosis of the coronary arteries is a question of very great importance in cardiac pathology; but the statements in works on anatomy differ, and even in special treatises upon the heart precise statements on this point are often wanting. It is quite certain in disease that one coronary artery is sufficient to maintain the nutrition of the heart. Cases are not very rare in which the mouth of one coronary artery is completely blocked by atheromatous change in the coats of the aorta, and still the heart's nutrition has for a long time been well provided for. In one such case which I have recently examined, the coronary artery, the mouth of which was completely obliterated, was of normal size and appearance even up to the obstruction, and contained blood, which must have been supplied to it from the unobstructed artery of the opposite side. In one of the later editions of Quain's Anatomy this note occurs, in small print:—"It has been customary to describe the transverse branches of the coronary arteries as anastomosing in the auriculo-ventricular sulcus, and the descending branches as anastomosing near the apex of the heart; and this description was never doubted until it was found by Hyrtl, as the result of separate injections of these vessels, that the branches of one coronary artery cannot be injected with material introduced into the other." This note has been removed, I find, from the last and recent edition, but there is still in the text a want of definiteness upon the point. With the view of satisfying myself I have lately made a series of injections of human hearts. The material I used was a mixture of carmine and gelatine, which was injected hot into hearts which had been thoroughly warmed in water. Some of these hearts were injected from the left coronary artery, and some from the right. In both cases the whole of the heart was beautifully injected, and microscopical sections showed that the injections had reached even the smallest capillaries. The injection passed with hardly any pressure, and with the greatest ease, into the vessels. So free was the anastomosis between the two coronary arteries, that on injecting into one artery the fluid ran in a considerable stream out of the mouth of

the other, and, by pressing in jerks upon the piston of the syringe, could be made to move also in jerks. The fact, then, of the very free and complete anastomosis of the coronary arteries is established. It is difficult to understand how Hyrtl could have arrived at such opposite conclusions. The most probable view is that he injected hearts recently removed from the body. The only failure which I experienced was with a heart injected as soon as removed. In this the injection failed to run over more than quite a small portion of the heart, not even over the whole of those parts to which the coronary artery injected was distributed. All the hearts, except this one, were macerated for some time in water, in order to get rid of all the blood-clots which might be in the vessels in the recent state. When this precaution is taken success is certain.

Wimpole-street, W.

THE CAUSATION OF CARDIAC AND PULMONARY DYSPNOEA IN DISEASES OF THE HEART.

By CHARLES STONHAM, M.R.C.S. Eng.,

Assistant Demonstrator of Anatomy in University College, London, and Clinical Assistant to the Western General Ophthalmic Hospital, etc.

In advanced cases of valvular disease of the left side of the heart in which there is want of compensation and pulmonary congestion with deficient oxygenation of the blood, dyspnoea is a prominent and very distressing symptom. The so-called pulmonary dyspnoea is persistent, and hitherto has been regarded as the consequence of pulmonary congestion with oedema of the lungs and pleurae. That these two conditions do certainly produce difficulty of breathing there can be no doubt, but I shall hope to show that there is a third cause constantly at work aggravating the condition, and moreover that this cause under certain conditions produces the paroxysms of cardiac dyspnoea. Attacks of dyspnoea, often of great severity, also occur from the impaction of an embolus in the lung, especially if it is of large size, but in such cases there is frequently a rigor, with high fever, pain in the side, and bloody expectoration. Such attacks are entirely different from those now under consideration, which occur just as the patient is dropping off to sleep. In its general characters the paroxysm simulates an asthmatic attack, but the breathing is more "panting" in character. The hypodermic injection of morphia ($\frac{1}{4}$ or $\frac{1}{2}$ gr.) at once gives relief, which is maintained for several hours afterwards. As yet this cardiac dyspnoea has not received any satisfactory explanation. Dr. J. Milner Fothergill, in his work on the "Heart and its Diseases" (2nd edition, p. 91), speaking of cardiac dyspnoea, says:—"... it is certainly connected with the descent of the diaphragm, and is occasioned by flatulence and fullness of the abdomen. In the horizontal position the contents of the abdomen press upon the diaphragm equally with the other portions of the abdominal walls; in the erect or sitting posture they fall away from the diaphragm by their own weight. Dr. Lauder Brunton teaches that in the supine position the diaphragm has to overcome the action of the abdominal muscles; when up only lateral pressure is called for. It is not suggested that this mechanical explanation is the full and complete explanation of orthopnoea." Now, in the first place, if flatus and distension play any part in the produc-

tion of cardiac dyspnoea, why does it occur when the patient is dropping off to sleep? Surely sleeping does not cause flatulence? And, secondly, with regard to position, cardiac dyspnoea certainly occurs with very great severity in patients who cannot lie down at all; but, at the same time, it is quite conceivable that this may play a part in its production, although, I should imagine, a very insignificant one.

With regard to Dr. Lauder Brunton's theory, it may be remarked that the abdominal muscles during orthopnoea, instead of hampering the action of the diaphragm, really help it, since they become indirectly inspiratory by fixing the lower ribs, and so allowing a more fixed point for the diaphragm to work from. And, lastly, I cannot see why morphia should act so quickly and beneficially if the above explanations are at all correct. We know from physiological experiments that the respiratory centre in the medulla oblongata is stimulated by the circulation of venous blood in it, and furthermore that it is the lack of oxygen, and not the excess of carbonic acid, that is responsible for this. Now, in those cases of heart disease in which cardiac dyspnoea is present there is pulmonary congestion; the blood generally is more venous than natural. This blood circulating in the medulla acts as a stimulus to it, and hence it is in a constant state of excitement, and more vigorous respiratory impulses are generated. I would submit that this condition of excitement of the centre combined with the congestion and oedema of the lungs, is the real cause of pulmonary dyspnoea.

Now, what further causes come into play in producing a paroxysm of cardiac dyspnoea? Firstly, let us inquire what happens during sleep, and then see if any changes occurring could influence the respiratory centre in any way. Sleep is brought about by cerebral anæmia, and hence the respiratory centre is less supplied with blood than during the waking hours, and therefore the oxygen going to it is still further lessened in amount, and the state of excitement is accentuated, and as a result the centre, which was before just kept within bounds, now breaks loose, so to speak, and a paroxysm of cardiac dyspnoea ensues. This explanation of the phenomenon is also borne out by the effects of treatment with the hypodermic injection of morphia. Morphia acts as a nervous sedative, lessening the irritability of the whole nervous system, central and peripheral, so that a greater stimulus is required to call forth any action. The irritability of the respiratory centre would accordingly be lessened, and hence the stimulus of the venous blood would not call forth such vigorous respiratory impulses. The dyspnoea would be relieved. Cheyne-Stokes' respiration, met with in cases of fatty degeneration of the heart, and sometimes in cerebral and renal diseases, has also been attributed to a want of oxygen. Professor Laycock thinks it is due to a sentient paresis of the respiratory centre not necessarily dependent on structural or other diseases of the heart, but Dr. Hayden goes further, and adds to this a want of oxygen; but Biot proved that the arterial circulation is increased, in some cases at least, during the apnoea, and not during dyspnoea. Traube held that it was due to over-action of the vagi by accumulated carbonic acid constantly stimulating their endings; this view is favored by Biot. Dr. Edis, however, says that this ascending and descending respiration is due to lessened irritability of the centre, so that carbonic acid is not sufficient stimulus.¹

NOTE ON MURUNGAI OR MURUNGAH.

By E. M. HOLMES, F.L.S.,

Curator of the Pharmaceutical Museum.

THERE can be no doubt, I think, that the plant known to Mr. P. S. Brito under the above names is the *Moringa pterygosperma*, Gaertn. The name is variously written by different authorities, as Marung-gai (Waring), Mooringay (Jesudasan), or Mooringhy (Drury), and the specific botanical name is the Latinized version of the same word. My friend Dr. Ondaatje, of Ceylon, informs me that it is called the "drumstick" tree on account of the curious pod-like fruit, which when ripe is white, and bears some resemblance to a bone or short stick. The properties of the plant closely resemble those of horseradish, for which Dr. G. Bidie regards it as a perfect substitute.¹ On account of this similarity it is called by the Anglo-Indians the "horseradish" tree. The leaves, flowers, and immature fruits are sometimes used as a culinary vegetable, and are considered by the native doctors in India of value in the treatment of diseases of the liver and spleen. The juice of the fresh leaves is employed to hasten the suppuration of boils. The fresh root is rubefacient and even vesicant, but its application causes great pain. The decoction of the root bark has been given as an emmenagogue, but is said to be liable to produce abortion. The rubefacient and stimulating properties of the plant are also turned to account in the treatment of paralysis and leprosy, epilepsy and hysteria. A great deal more might be said about the medicinal properties of the plant, but all that could be adduced might be summed up in the above quoted opinion of Dr. Bidie. The plant yields a volatile oil, to which its properties are believed to be due. The oil has a very disagreeable odor, and is said by Bronghton to be different from either oil of mustard or oil of garlic.

Dr. Ondaatje informs me that so far as his knowledge extends, and he has practiced in Ceylon for thirty-six years, the leaves of the drumstick tree are never used in that island in the treatment of hydrophobia, nor is the plant known by its Malay name, Marung-gai, nor its Tamil name, Mooringa, but by the Hindu one, Sohunjana. He is of opinion that the leaves would not have the slightest therapeutic value in the treatment of hydrophobia. The tree is a very interesting one from a botanical point of view, being allied to the Leguminosæ in habit, and, indeed, was erroneously included by Linnaeus in the genus *Guilandina*. It resembles the plants of this family in having compound leaves, stipules, and flowers which chiefly differ from those of the tribe Cæsalpinieæ in the odd petal being inferior, in the one-celled anthers, tricarpeillary, ovary, and anatropous ovules. In the last two characters it approaches Violaceæ as well as in the three-valved fruit, parietal placentation, and hollow apex of the style. In properties it resembles the Cruciferae, Capparidaceæ, and Resedaceæ. By Grisebach it was placed in the Capparidaceæ and by other botanists it has been compared with the Polygalaceæ, Bignoniaceæ, and Sapindaceæ. In the classical "Genera Plantarum" of Benth and Hooker it follows Sapindaceæ as an anomalous genus of doubtful affinity. It is not surprising, therefore, that from description alone Dr. Trail should have referred "Murungai" to the Leguminosæ. Specimens of the pods and root bark can be seen in the museum of the Pharmaceutical Society of Great Britain.

REMARKABLE EFFECTS OF MASSAGE ON GASTRIC ASSIMILATION AND NERVOUS DEBILITY.

By J. BERESFORD RILEY, M.D.

WITH the exception of salicin and its compounds for rheumatic fever, there has not been, I venture to say, any therapeutic discovery of recent times so brilliant in its results as massage in the treatment of functional neurasthenia by Dr. Weir Mitchell, of Philadelphia, and the profession is much indebted to Dr. Playfair for its systematic introduction into this country about two years ago. I was so struck at the time with his article on the subject in *THE LANCET* that I determined to give it a trial on the first opportunity, and for this I had not long to wait, inasmuch as a typical case presented itself for treatment shortly after. About the middle of June, 1881, I saw, in consultation with my friend, Dr. Hine, of Leytonstone, Miss A. C—, aged twenty-one, who for four years previously had been more or less a complete invalid. At the time of my visit she was much emaciated and very anæmic, had a small, sluggish pulse, and an extremely apathetic expression of countenance; her menstrual periods were very irregular, and their character most capricious, being sometimes dysmenorrhagic and scanty, and at others profuse and painless. She had no appetite whatever, and for many months "had not taken sufficient food to keep a baby alive," her chief articles of diet being a little Nestlé's food or arrowroot and occasionally a few spoonfuls of beef-tea. The least particle of meat or vegetable gave her intense gastrodynia, which usually ended in noisy retchings until the offending matters were brought up. She had frequent attacks of dyspnoea, often followed by a kind of cataleptic swoon, which sometimes lasted for hours. For the last twelve months she had passed the greater part of her time in bed, and almost exclusively occupied the services of a most self-sacrificing sister. "The doctor was never out of the house on her account," and the whole family were in a chronic state of alarm at the constantly recurring prospects of her speedy demise. I felt that it would be unwise to at once propose massage in a highly nervous case like this, and so, after temporizing for a while, I gradually obtained the consent of the family to this mode of treatment, and for that purpose she was admitted into the Finsbury Home Hospital for Gentlewomen on July 13th. It is unnecessary for me to recapitulate the various steps of this proceeding, as they have already been so graphically described by the author in his little work, "*Fat and Blood, and how to make it.*" It will therefore be sufficient for me to state that after the first week all her abnormal symptoms began to disappear with a rapidity that was truly marvellous, that at the end of the second she was eating and digesting a quantity of food that was almost incredible, and that she left the hospital within two months with an appearance of health, strength, and energy that astonished those who had known her previous condition. She gained flesh and color rapidly under treatment, but I am sorry that I had not the means of ascertaining the exact amount of the latter.

The next case is that of a young married lady, twenty-one years of age, who had been under my care for some time for general debility, dyspepsia, and cervical catarrh, the results of a miscarriage eighteen months ago. She was a bright, intelligent patient, and felt acutely her constant drawbacks to the enjoyment of an easy and pleasant social position. She had no symptoms or

history of hysteria, and had been fairly strong until the time alluded to, but since then had gradually lost strength, was fatigued on the slightest exertion, and suffered intensely from acute gastrodynia without any apparently correlative cause. She made but very unsatisfactory progress towards recovery until she commenced treatment by massage on Nov. 10th, 1881, when the dyspeptic symptoms quickly disappeared, from which she has not since suffered, and she left the hospital within six weeks greatly improved in her health.

The third case I will briefly describe as that of a lady, thirty years of age, who had become feeble and dyspeptic from the conjoined effects of rapid child-bearing, menorrhagia, from subinvolution, and chronic ulceration of the cervix uteri. After a very protracted term of treatment, with but little reparative effort on the part of her constitution, the primary causes of her illness were nearly all removed, but she still remained in a very weak state, and suffered much from gastrodynia and the many other morbid symptoms of a feeble digestion. Medicines, and carefully carried-out dietetic rules, did her but little good, but in a few weeks, under the massage treatment, she improved rapidly; the thickly coated tongue became clean for the first time during my knowledge of her, and she left the hospital within a month, having made more progress during that time than almost the whole period anterior to it.

I feel that it would be wearisome to reiterate the history of all the cases that I have treated in this way; and so will content myself by expressing an opinion, founded on them, that in all cases of functional nerve prostration, and its various morbid consequences, massage will seldom fail to effect a rapid cure, and that its influence upon the assimilative and digestive functions of the stomach is especially remarkable; its effectiveness in other forms of disease has yet to be proved, but I am inclined to think that its application will have a much wider range than has at present been assigned to it, and that it will be supplementary to other treatment in most cases where long-continued rest is necessary. I am employing it at the present moment in this way with great advantage in a case of fibroid degeneration of the uterus, with severe and long-standing menorrhagia. The marked anemia is rapidly improving under its influence, the flesh becoming firmer, and the appetite and digestion greatly increased. It appears to do good also in another way—namely, by employing the patient's mind, and thus relieving the monotony of the recumbent position when long maintained.

I think I have already borne sufficient testimony to the value of massage in all functional derangements of the nervous system, but I have two cases under my care at the present moment which are such striking examples of its efficacy that I will ask to be allowed briefly to record them.

One is that of a young lady, about twenty-three years of age, the daughter of a Norfolk clergyman, who was sent to me three weeks ago suffering from hystero-epilepsy, with hysterical paralysis of a remarkable nature. She had been the subject of epilepsy since thirteen years of age, and had had an attack at night for many months, at least once a week. Since beginning treatment there has not been a single seizure, and the hysterical paraplegia, with incontinence of feces and urine, which prevented her from standing without assistance, has been so far relieved that she walked to church on Easter Sunday with one of the nurses. It may be said that ordinary treatment under bromide of potassium would have been as effectual, but though I admit that the epilepsy might have been equally well controlled by such means, I cannot

think that so pronounced a paralytic symptom would have yielded in so short a time.

The other case is that of a maiden lady, thirty-five years of age, who I went over to Holland to see in consultation with Dr. Van de Noorda, of La Hague, under whose care she had been for two years. She had also seen the celebrated Dr. Mezza, of Amsterdam, but all their remedies combined had failed to do her any good, and at the time of my visit she was getting rapidly worse, and had not left her room for more than a month. It appears that owing to over-study and too close application to her scholastic duties she had broken down and become so nervous and whimsical as to be a misery to herself and a source of worry and anxiety to all around her. The case was quite easy to understand—the old story of mental strain and nervous shock, without any physical disease whatever. I felt sure that massage and change of scene were the only means of saving her from the death or insanity that she believed would be the sole terminations to her sufferings, and with the consent of her friends and after a great deal of persuasion on my part she came over with me to London three weeks ago for that purpose, and is already able to walk about by herself, eat well, sleep better, and take an interest in life and her surroundings.

Finsbury-square, E.C.

CASE OF INTESTINAL OBSTRUCTION FROM VOLVULUS TREATED BY ABDOMINAL SECTION.

WITH REMARKS ON THE OPERATION.¹

By J. KINGSTON FOWLER, B.A., M.B., etc.,

Assistant Physician and Pathologist to the Middlesex Hospital; Assistant Physician to the Brompton Hospital for Consumption.

HENRY F—, aged forty, a wine porter, was admitted into the Middlesex Hospital under my care on August 7th, 1882, suffering from intestinal obstruction. His history up to the present attack presents no feature of interest. He has for some years worn a truss for double inguinal hernia; both ruptures are easily reducible, and have never caused him any serious discomfort. On August 3rd, about 6 P.M., whilst at work, he was suddenly seized with a severe pain just below the umbilicus; this was relieved by the application of hot flannels. On the 4th, his bowels acted slightly in the early morning, but since then nothing has passed per anum. He continued at work until the evening of the 5th, vomiting five to six times during the day, suffering from some abdominal pain, and being unable to take food. He then took to his bed, and remained there in much the same condition up to his admission at 7 P.M. on August 7th. He has passed very little urine. He has been under medical treatment, which appears to have consisted chiefly in the administration of castor oil and other purgatives.

On admission the patient was much collapsed, the expression was anxious, and the features pinched. The inguinal herniæ were easily reducible; the abdomen was moderately distended and tympanitic; no tumour could be found, and on examination of the rectum nothing abnormal was detected. The pulse was 76, small and compressible. There was some bronchial râles over both bases posteriorly. Shortly after admission he vomited twice, the vomited matters having a distinctly faecal odor.

I saw the patient at 8 o'clock, and ordered a large enema of warm water. Whilst this was being injected I auscultated the colon and cæcum, and distinctly traced the fluid as far as the right iliac fossa; beyond this point no gurgling was audible. On removing the enema tube the greater part of the fluid regurgitated unchanged. After a consultation with Mr. Hulke it was decided to open the peritoneal cavity at once, and search for the obstruction. Ether having been administered Mr. Hulke made an incision from an inch below the umbilicus downwards to within about two inches of the pubes, and exposed some dilated and rather congested coils of small intestine. The finger was passed into the abdomen, and the open inguinal canals carefully examined, and found to be empty. The site of the obstruction could not be ascertained. From the pelvis a collapsed portion of the ileum was withdrawn, and whilst the distended bowels were prevented from escaping Mr. Hulke proceeded to examine the collapsed portion piece by piece, a single loop only of bowel being exposed at a time. Very soon some coils were found adherent to each other, forming continuous V-shaped curves, like a "cracker;" their perpetual covering was thickened, the result of the old limited peritonitis. As the bowel beyond was still collapsed this was clearly not the site of the obstruction, and the examination was continued. A little further on a sense of resistance was felt; this was overcome by moderately firm traction, and immediately a marked change was noticed in the appearance of the bowel. Instead of being pale, contracted, and empty, it was now distended, of a rather dark purple color, and contained air and fluid. A narrow ring of deeper congestion was also noticed, and about eighteen inches further the bowel presented a similar appearance. As we now felt confident that the obstruction had been relieved, probably by the untwisting of a volvulus, it was decided to cease any further examination. The abdominal wound was closed by sutures, and a pad placed over each hernial opening. After the patient had been in bed about a quarter of an hour, there was a return of faecal vomiting. Half a grain of extract of opium was given by the mouth, and he was ordered an ounce of brandy in iced water immediately, and to have ice to suck at intervals. At 12.30 A.M. he again vomited faecal matter. A hypodermic injection of one-sixth of a grain of morphia was administered. At 9 P.M. there was a slight return of the vomiting, but it had lost its faecal character; he had slept at intervals during the night. He had no pain, and said he felt comfortable. The morphia injection was repeated, and he was ordered a mixture containing bicarbonate of soda, dilute hydrocyanic acid, and infusion of calumba, and a teaspoonful of brandy in iced water every three hours. He was kept during the day partially under the influence of morphia, and there was no return of the vomiting until midnight, when he was slightly sick after taking some brandy in milk and limewater. On the following morning (9th) it was noted that he had passed a good night, and had not vomited. The pulse was 96, full, and firm; the tongue was moist and furred; he said he felt much stronger. He vomited again at 10 A.M., but it was not faecal. He was ordered half an ounce of iced champagne every quarter of an hour, and Brand's essence frequently. Nutrient suppositories had been administered every four hours since the previous evening. At 4 P.M. he passed a copious semipultaceous motion, only slightly colored with bile, and subsequently two similar-looking stools. About 5 A.M. on the morning of the 10th he became much collapsed, wandered, refused food, and gradually sank at 12.45 P.M.

¹ Read before the Medical Society of London, Jan. 15th, 1883.

At the post-mortem examination the abdomen was moderately distended, and the edges of the incision were united by plastic exudation. There was no peritonitis. A portion of the ileum, eighteen inches in length, situated about two feet from the ileo-cæcal orifice, was somewhat congested and slightly diseased; the peritoneal coat was smooth and shiny. The whole mesentery was very long, measuring from seven to eight and a half inches from the spine to its attachment to the intestine. There were some pleural adhesions on both sides, and over the right lower lobe there was a little recent lymph. The lungs were crepitant, except the right lower lobe, which was completely consolidated, and in a condition of red hepatization. There was an excess of subpericardial fat over the right ventricle; the left ventricle was dilated, the muscular tissue soft and slightly fatty; there were some deposits of fat beneath the endocardium. The kidneys were congested, but otherwise normal.

Remarks.—One object which I have in view in bringing this case before the Society is to draw attention to some points in the treatment of certain cases of intestinal obstruction which I think of great importance. The first is the auscultation of the colon and cæcum during the administration of an enema. This should never be omitted, as it often affords valuable information as to the site of the obstruction, and so to some degree indicates the line of treatment to be followed. If during the injection the fluid can be distinctly heard gurgling in the cæcum, it may be considered almost certain that the obstruction is in the small intestine. If the flow of fluid is stopped at some intermediate point in the colon, it is very probable that the obstruction is situated at that spot, but the indication is not so certain, as a case is recorded in which fluid injected into the rectum flowed out as fast as it was poured in, and this being taken as an indication that the sigmoid flexure was the site of the obstruction, colotomy was performed in the left loin. On the patient's death from continuance of the obstruction, its site was found to be the small intestine. A possible fallacy in this test is that the movement of fluid in the bowel beyond the obstruction, owing to increased peristalsis, may be mistaken for the gurgling sound produced by the fluid injected. In the last four cases of obstruction, however, which I have met with, and have seen this test used, it has given trustworthy indications. I have lately repeated the experiments on the cadaver made by A. Hall in 1846, and by others since with the view of testing the competency of the ileo-cæcal valve, and find that on injecting water into the colon its passage into the ileum is arrested at the valve, and that the greater the tension of the fluid in the cæcum the more closely are the edges of the valve approximated. In one experiment some air passed through the orifice; this is probably due to the fact that in the cadaver the normal tonicity of the sphincter is lost. I think there can be no doubt that the ileo-cæcal valve in the living body under normal conditions does effectually prevent the passage of fluid or air from the cæcum to the ileum. I am aware that cases are recorded tending to prove that as the result of an anti-peristaltic action fluid and solid materials injected or placed in the rectum have passed the ileo-cæcal valve; but even if this be so, it does not follow that any mechanical effect can be produced on the interior of the small intestine by rectal injections. If therefore the obstruction appears to be in the small intestine, it is useless to persevere with enemata, the only effect they might possibly produce being an increased peristalsis in the lower portion of the

ileum, and all authorities agree that one object of treatment in intestinal obstruction is to diminish as much as possible the excessive peristalsis. If, however, the obstruction appear to be in the colon, there is a fair chance that it may give way before the continued use of warm enemata, or inflation of the bowel with air. Under almost all circumstances it is advisable to get the patient partially under the influence of morphia without delay, thereby checking the vomiting and peristalsis, relieving the pain, and warding off the onset of collapse.

There is some danger that the comparative calm thus induced may tempt us to postpone those operative measures by which alone in many cases the patient can be permanently relieved. This remark applies especially to cases of acute internal strangulation of the small intestine, which are extremely fatal. I have a strong conviction that this mortality might be diminished if resort were had to the operation of abdominal section before the patient's strength has been exhausted by constant vomiting. On looking back at this case, one's only regret is that the operation was not performed earlier; had it been, it is quite possible that a life might have been saved. In this, as in so many similar cases seen in hospital practice, valuable time had been lost before the patient's admission, the result being that although the operation was completely successful in relieving the obstruction, and was not followed by peritonitis, the patient sank from exhaustion. Speaking generally, the results of this operation cannot be said so far to have been very encouraging, but still a fair number of successful cases are on record, and the number is steadily increasing. The danger of the operation in my opinion arises chiefly from the manipulation of the distended intestines; this in the most careful hands is very liable to produce partial or complete rupture, an accident which in my own limited experience has happened three times to distinguished surgeons.

So far as I have observed the operation is usually performed in the following way:—The peritoneal cavity having been opened by an incision of the required length in the linea alba, between the umbilicus and the pubes, the fore-finger is passed in and careful search made for the cause of the obstruction. If this cannot be found, the operator proceeds to examine the whole length of the bowel, beginning with the portion of small intestine presenting at the incision; with one hand he withdraws a further portion and with the other returns the part already examined. Unfortunately there is no means of telling whether the bowel is being examined in the direction of the duodenum or of the cæcum. At one operation which I witnessed, after about fifteen feet of intestine had been examined, the duodenum was reached, when it became necessary to reverse and repeat the whole process. This done, it was evident that had the bowel been examined in the opposite direction the obstruction would have been reached almost immediately, an unfortunate but, under the usual mode of operation, unavoidable occurrence which prolonged the operation by nearly half an hour. It is obvious that such an amount of exposure and handling of the intestines as this method involves must greatly increase the risk of peritonitis and rupture. And beside the danger from peritonitis, rupture of the bowel, and shock of a prolonged operation thus entailed, there is, I believe, another risk, less serious, but still to be avoided if possible. It is this. Let us suppose the examination of the intestine to have been commenced at some point between the obstruction situated in the small intestine and the duodenum, and continued in the direction of the latter. As the successive

portions of bowel are withdrawn, the contents are gradually carried onward to the pylorus, and regurgitate into the stomach, where their presence must add to the already existing depression, and diminish the chances of recovery. In the case to which I have just alluded, where death occurred soon after the operation, and without any recurrence of vomiting, the stomach was found to contain more than two pints of fluid, which had evidently regurgitated from the intestine, possibly in the manner I have just described. In the performance of the operation of laparotomy, it should, I think, be laid down as an absolute rule that the distended bowel is only to be manipulated in case the surgeon after a most careful search is unable to find any contracted bowel; and I am not quite sure whether in such a case the patient's chance of recovery would not be almost as good if the operation were abandoned, and full doses of morphia administered.

There are many advantages in dealing with the collapsed bowel only; one is that it can be examined with much greater ease and in far less time than it takes to overlook an equal length of distended intestine; another is that if a considerable length be exposed at one time, there is no difficulty in returning it into the abdomen. There is no more painful sight than that of a surgeon struggling with a mass of intestines which, in spite of all care, have slipped out of the abdomen and refuse to return; as fast as one portion is replaced another escapes, and in the end he may be considered fortunate if the bowel does not rupture, or if he is not compelled to puncture to allow the gas to escape; a proceeding which, although considered by some to be entirely without danger, had much better be avoided, if possible. Another advantage of this method is that the collapsed intestine never leads to the duodenum; and, most important of all, there is much less risk of peritonitis resulting from exposure and handling of the collapsed bowel.

If, then, there be advantages in dealing with the collapsed bowel only, it becomes of great importance to know where it is likely to be found. The distended abdomen is tympanitic, and when it is opened distended bowel is always seen on the surface. This is only what might be expected: the air-containing portion naturally rises to the surface.

In making post-mortem examinations I have been struck with the fact that if the upper portion of the small intestine be distended, the lower and collapsed part of the ileum is nearly always seen lying in the pelvis. I believe that the same condition obtains in strangulation of the small intestine, and that the collapsed portion of the bowel, which it is of so much importance to secure, will in these cases be found in the pelvis, and may be most easily reached towards the right side. I ventured to suggest to Mr. Hulke before he commenced the operation that he would probably find the collapsed bowel in the pelvis, and on passing his finger deeply down he at once brought out a portion of the lower contracted end of the ileum. I have not been able to find any record that attention has already been drawn to the point. The explanation I believe is that during the violent and continued peristalsis and gradual distension of the bowel above the obstruction, the smaller and less active portion of bowel below, after expelling its contents, is forced downwards into the pelvis, whilst the distended, and therefore specifically lighter, portions rise to the surface. The pelvis also is too small to hold a distended loop. Another point to which I should like to call attention is that in cases of internal strangulation from bands care should be taken to make sure that the band di-

vided is the cause of the obstruction, and that there is not another present in the immediate neighborhood, which, if not assisting in the present, is at any rate a possible source of future trouble. I have lately met with two cases where at the autopsy a second band was found close to the divided one. I do not, however, think that the possible existence of a second band is of sufficient importance to justify any handling of the distended bowel when the immediate cause of the obstruction has been ascertained. It is not possible within the limits of this paper to discuss thoroughly the diagnosis and treatment of the different conditions which may give rise to intestinal obstruction. The various rules for distinguishing between obstruction of the large and small intestine are well known, but a very limited clinical experience is sufficient to teach one that cases are met with which transgress all rules and almost defy diagnosis, both regional and pathological. I have contented myself with drawing attention to a few points which appear to be important.

TUBERCLE BACILLI IN THE URINE.

By R. SHINGLETON SMITH, M.D., B.Sc., M.R.C.P.,
Physician to the Bristol Royal Infirmary.

THE following case has recently come under my observation, and is worthy of record.

A male patient, aged nineteen, who began to have symptoms of bladder disease at the age of fifteen, and for which he had been under frequent treatment ever since, was laid up early in February of this year with cystitis. I was asked to see him on the 25th of March, in consequence of other symptoms pointing to disease of the lungs. He had been wasting since Christmas, and now had a cough with high temperature, but at no time had hæmoptysis been observed. Mr. Greig Smith suspected there must be some commencing disease at the apices of the lungs, and found that the percussion note below the clavicles was not clear. A few days after this was remarked it was found that one of the rarer accidents of phthisis had occurred, and that there was subcutaneous emphysema across the upper part of the chest, and involving the loose cellular tissue of the neck. At the time of my visit, in consultation with Mr. Greig Smith, the patient was found to be much emaciated, with a hectic flush and a temperature (5.30 P.M.) of 103°. He had an occasional cough, but no expectoration. His principal complaint was a frequent desire to micturate, and pain in doing so; he could not go longer than two hours, and the passage always gave him acute pain. There was also occasional diarrhoea. On examining the chest there was the well-marked crackling of subcutaneous emphysema across the upper part of the thorax down to the third rib on both sides, and extending up the neck on both sides as high as the inferior maxilla and round to the occiput. The percussion note did not appear to be abnormal. The presence of air in the cellular tissue had altogether obscured the dulness of the percussion note which had been observed the day before. With the stethoscope coarse crepitation could be heard below and above both clavicles, as well as in all parts to which the air had extended. The presence of this emphysema crepitation quite obscured all other lung sounds; no bronchial breathing or bronchophony was present. The general condition of the patient, and the fact that emphysema had taken place, led to the conclusion that there was probably tuberculous disease in the lungs, but the hectic associated with the bladder symptoms appeared to be the predominating

feature. On April 2nd I again saw the patient, and continued to see him each day till his death nine days later. There had been a very marked change since my first visit. The emphysema had entirely disappeared, and now it was evident that there was considerable disease in the upper lobes of both lungs; there was marked dullness on percussion from the clavicle to the third rib in front, and at the supra-spinous fossæ behind; there was also coarse, bubbling crepitation, as of breaking-down lung, both in front and at the back of both upper lobes. There was frequent cough, but no expectoration; patient said he could not expectorate, but on being urged to try he coughed up and spat out on the handkerchief a plug of thick, yellow, tenacious, purulent matter, resembling the nummular sputum of phthisis, and which was found to contain immense numbers of tuberculous bacilli. The temperature was high, above 102°, and there was diarrhoea as often as five or six times in the day. The urine was copious, cloudy, with sediment of pus, but no casts, and only a trace of albumen; no blood.

It was now clear that the lung disease was of an active tuberculous character, and that this was the principal cause of the hectic and rapidly failing strength; but it occurred to me that it would be of some interest to examine the purulent urine for bacilli, as the cause of the disease in the bladder had been somewhat obscure, and had been suspected to be of a tuberculous nature. The only evidence of phthisis in the family was that his father died at forty-nine, after being ill for some years with what is called "bronchitis." On April 4th I obtained some of the urine for examination. It had a sediment of pus-corpuscles, amounting to about one-twentieth of the bulk of the urine, and about one-eighth of albumen; there was no trace of blood, and no casts or blood-corpuscles could be seen. On allowing a little of the sediment to dry on thin glass circles, and on treating them exactly as sputum is treated in testing for bacilli by Ehrlich's method, with the aniline gentian fluid, I had no difficulty in detecting a few bacilli on each of the slides. They were not numerous, and although I had myself no doubt of their presence, I thought it might be difficult to convince a less easily satisfied observer. On the following day I obtained another specimen of urine with characters much as before. On searching for bacilli in the same manner, I again found unquestionable evidence of their presence on each of the thin glasses which I had prepared. I have now before me three mounted slides, each one of which contains an average of three or four tuberculous bacilli in any one field, readily seen with Hartnack, No. 7, and ocular 4. The largest number counted in one field is twelve, and in many parts of the slides none are visible; they are not therefore numerous, as in most specimens of tuberculous sputum, where they are seen at a glance in great numbers, but they have to be looked for with some care. Their appearance is exactly similar to the bacilli found in the sputum of the same patient; they are well formed, of full size, spore-lated, and invariably isolated. One is found here and there, rarely two close together; no groups or masses are seen such as may be found in sputum—or better, in the caseous matter lining the cavities of lung. They have no connection with the pus cells amongst which they are found. No putrefactive or other bacilli are visible on the slides, inasmuch as they were treated with nitric acid (1 to 2), and so everything has the blue color redissolved from it except the bacilli; those therefore have the same appearance, dimensions, and chemical staining characters which are indicative of the bacilli of tubercle, and when treated in the same way the

bacilli of the urine exactly resemble those of the sputum of the same patient. On April 6th the patient's strength was rapidly failing; he was delirious, and passed urine in the bed almost unconsciously; on one occasion about two ounces of almost pure pus was passed, with much straining and with a great deal of pain. This was put aside and carefully examined, but although a dozen slides were prepared in exactly the same manner as before, no one of them contained anything which could be certainly identified as a bacillus. The patient became more and more unconscious, and gradually weaker; there was no exacerbation of cough or dyspnoea, not much pyrexia, and no return of diarrhoea. The urine continued to flow freely in the bed at longer intervals, and was clearer than before. Death took place from gradual exhaustion, on April 11th, 1883. Post-mortem examination was not allowed.

This case is probably one of the first in which the occurrence of tuberculous bacilli has been observed in the urine, and it is to be regretted that the friends of the patient would not give their consent to such an examination as would clear up any doubt as to the original nature of the bladder disease. That the immediate cause of death was acute tubercular phthisis, superadded to the debility induced by protracted hectic from bladder disease, there can be no question. The surgeon who formerly attended the patient believed the case to be one of strumous, probably tuberculous, disease of the urinary organs, and the examination of the urine during the last week of life quite bears out this view. It may be said that the few bacilli found in the urine may have been introduced accidentally from the air of the apartment, or may have been expectorated. Neither view will bear criticism, inasmuch as there was no expectoration at any time, excepting when the patient was urged to cough for the purpose. The nurse and the mother of the patient deny the possibility of this latter view. Moreover the urine was at once removed to the adjoining bath-room immediately after its passage. If the former hypothesis be adopted, it necessitates the existence of vast numbers of the bacilli in the air of the room in order that each drop might contain the numbers seen by the microscope. Doubtless the patient exhaled bacilli freely, as shown by Dr. Ransome to be the case with other phthisical patients; but the urine was not exposed to the air of the room for more than a few minutes, and the ordinary sediment in a medicine bottle of the urine could not contain such numbers as the few seen must imply. Furthermore, the urine passed on another occasion, that consisting of pure pus, did not contain bacilli, as it would be likely to do if those previously observed had been derived from the air in the room. It may accordingly be assumed that the bacilli found in the urine were discharged from the urinary passages. There were no symptoms and no evidences of any disease of the kidneys, but the whole history of the case in its early period was one of urethral and bladder mischief. It would be interesting to know whether at this period the urine contained tuberculous bacilli, but at this date Koch's great discovery had not been made. Probably the introduction accidentally or incidentally of the bacilli from without by means of the urethra may have been the first cause of the whole train of subsequent events. Tuberculous bacilli have been observed in the urine by Professor Rosentstein, of Leyden, in a patient whose symptoms had been of five years' duration, and it is interesting to observe that in the case now reported the bladder symptoms had been of four years' duration before the lungs became implicated, the latter having pre-

ceeded death by only four weeks. What the route was by which the lungs became infected we can only surmise. There is no evidence of any direct infection from communication with other patients, and it is probable that the source of infection was internal by means of blood and lymphatic vessels; the fact that the disease commenced in the apices of both lungs simultaneously quite bears out this view.

Clifton.

ON A CASE OF OBSTRUCTIVE JAUNDICE OF AN UNUSUAL NATURE.¹

By H. MALLINS, A.B., M.B., M.Ch., T.C.D.

M—, an officer in the Indian army, who had served during the Afghan campaign of 1878-79, proceeded, on the renewal of the war on Sept. 13th, 1879, to Dhaka, a fort situated at the Afghan end of the Khyber Pass. While stationed there he enjoyed good health until Oct. 13th, when he was attacked with intermittent fever of a very mild type. The attack, however, an unusual event in his case, was attended with a good deal of nausea and vomiting. Two days subsequently a decidedly yellow tinge of the conjunctivæ was noticed, and a week later well-marked jaundice was developed, with its usual accompaniments of whitish stools, dark-brown urine, etc. The appetite was not much impaired, but the ingestion of nearly every kind of food procurable was attended with so much subsequent nausea that the amount of nourishment taken was extremely small. Three weeks after the full development of jaundice, yellow vision and intense irritation of the skin, particularly that of the lower extremities, were complained of. No enlargement of the liver could be made out; very slight tenderness on pressure over the region of the gall-bladder was the only local indication. On Dec. 4th the emaciation, due no doubt to the want of sufficient nourishment, had become so marked that, acting on the counsel of his medical advisers, he returned to India to try the effect of a change to a hill climate. After a month's residence at one of the hill stations, there being no amelioration whatever in his condition, he applied for and obtained furlough to Europe. Several days delay occurred at Bombay prior to his embarkation. The second day after his arrival at that city, Jan. 18th, he had occasion to go to the closet, and while inspecting the excreta, as had been his wont since the commencement of the attack, discovered, to his great surprise, a large *ascaris lumbricoides*, apparently dead, one end of its body, to the extent of half an inch, being of a deep green color. The very next day the stools began to exhibit a slight amount of the normal bilious hue. Ten days after embarkation their color was quite natural, and before landing in England convalescence was satisfactorily established.

Remarks.—The subject of this record had undergone all the privations of the campaign of the previous year, including those of the terrible march back in June, historically known as "the march of death." It is more than probable that in quenching his thirst with some roadside water of doubtful quality he swallowed the ovum of the parasite with which he subsequently became infected. The immediate reappearance of bile in the stools which followed its expulsion, and the deep staining of one end of the parasite, render it very probable that in its migrations it entered the ductus communis, thus effectually plugging it and preventing the flow of bile. The mechanical

nature of the obstruction readily explains the failure of every remedy that was tried. The practical point deducible from the foregoing case would seem to be, that when a case of persistent jaundice—this case lasted exactly three months—is met with, in which no organic disease of the liver can be made out, and where there is no constitutional dyscrasia which would account for the symptom, the possibility of the plugging of the common bile-duct by a round worm should not be overlooked. There can be but little doubt that a few doses of *santonine* would have materially abridged the duration of the case above recorded.

Watton.

FRACTURE OF THE LARYNX BY DIRECT VIOLENCE.

By JAMES OLIVER, M.B.,

House-Physician to the Hospital for Women, London.

FRACTURE of the larynx by direct violence is an accident of so infrequent occurrence, and one which from a medico-legal point of view is of so great interest, that I deem it worth while to mention a case which recently came under my notice. The thyroid cartilage in its normal state is of such a structure that interference with its continuity can only result under very untoward circumstances. Like other structures of a similar nature in the human frame, however, the laryngeal cartilages are liable in advanced life to become the seat of ossific deposit, and then to be more easily fractured. The injury in my case had evidently resulted from the free use of a piece of wooden rail. The post-mortem appearances were in every respect those of death by suffocation, and need no mention. The larynx, with the pharynx, tongue, etc., were removed *en masse*, and examined. The thyroid cartilage, more especially the right half of it, was broken up into many pieces, one of which hung free in the lumen of the tube, evidencing great violence. Ossific change was very extensive. Corresponding with the inferior border of the body of the lower maxilla was a wound, incised in appearance, running from the middle line outwards to the left, and extending for about three inches. The wound was gaping, and exposed the bone for about an inch and a half. The left extremity of this wound was deeper than the right, and running from it was a smaller one, half an inch in length, directed towards the left angle of the mouth, and almost at right angles to the large wound. The junction of the two wounds had a thready appearance; they were apparently caused by a blow against the hard bone underlying. A small linear abrasion, about a quarter of an inch in width, could be detected on the skin over the prominent part of the thyroid cartilage, and which corresponded closely with others very similar, but much more extensive, on the scalp. The facts taken together all pointed to fracture by direct violence. Throttling is the more usual cause of fracture of the larynx; but when death results in this way the assailant usually maintains his grasp of the neck till the victim shows no sign of life, should circumstances permit of such. We must not, therefore, when this is the cause of death, expect to find ecchymosed spots over the larynx; for the blood being pressed out leaves parchment-like marks of a contused appearance, to which the blood never returns.

THE Duval Prize of the Paris Society of Surgery has been awarded to Dr. Deanos for an essay on "Lithotripsy in Prolonged Sitzings."

¹Read before the Norwich Medico-Chirurgical Society.

ON A CASE OF AN ENORMOUS MYXO-LIPOMATOUS TUMOUR WITHIN THE ABDOMEN.

By JOSEPH WIGLESWORTH, M.D. Lond.

Assistant Medical Officer Rainhill Asylum.

I AM indebted to Dr. Rogers for permission to publish the notes of the following case:—

Louisa B—, a congenital imbecile, aged forty-three, had been an inmate of Rainhill Asylum for twenty-seven years. She was short in stature, and of spare habit. She had very little intelligence, was almost destitute of the faculty of speech, and though usually quiet and orderly, displayed at times pugnacious tendencies. When she first came under my observation in October, 1879, she was suffering from a large abdominal tumour. This had been first noticed about twelve months previously; it was, however, then of considerable size, and had, as is so usually the case in demented patients, been accidentally discovered, the patient herself having in no way called attention to it. In November, 1879, she being then confined to bed, her abdomen presented the following characters. It was pretty uniformly distended, and measured round its most prominent part 39½ in.; distance from anterior superior iliac spine to umbilicus, right side, 10½ in.; left side, 9½ in.; whole of right side of abdomen dull on percussion, the dullness extending superiorly to within 3 inches of ensiform cartilage, and laterally across the median line to left flank, which, however, was resonant; fluctuation very distinct all over the tumour, not, however, extending from one side to the other, being apparently limited in various directions by septa. The patient had a constant cough and there were crepitant râles at the base of both lungs. On December 2nd the greatest circumference had increased to 40 in., the patient had become much more feeble and emaciated, and respiration was more embarrassed. On March 10th, 1880, the girth of the abdomen had increased to 43 in., the umbilicus was now obliterated, and the superficial veins of the abdomen and chest, chiefly on the right side, had become distended; the fluctuation wave was still very distinct; œdema of feet had also appeared. From this time the various pressure symptoms rapidly increased in intensity; the superficial veins of the abdominal walls became enormously distended and exhibited changes of distension in response to respiratory movements, collapsing on inspiration, and becoming distended on expiration; the superficial veins of the chest and neck were also enlarged, and both lower extremities were much swollen from œdema; the breathing continued to get more embarrassed, and she gradually sank and died on April 25th, 1880.

Autopsy.—It is unnecessary to describe the contents of the cranium, and as regards the thorax it may be simply stated that the costal arch was considerably expanded; the arch of the diaphragm reached to the lower border of the third rib on the right side, and the lungs were very œdematous, the structure of the right being much compressed and tough, though crepitant. Abdomen: The greater portion of the abdominal cavity was occupied by an elastic tumour, which was everywhere adherent to the abdominal walls and to the surrounding viscera. The colon was firmly adherent to the left border, and the small intestines—pushed over to the left side—and stomach were adherent in other parts. The anterior margin of the liver was flattened over the tumour to a depth of about three inches, and so thinned as to be in places not more than a line in thickness. The tumour had no very distinct pedicle, but the ad-

hesions appeared stronger and thicker towards the pelvis; it weighed on removal, 41½ lb.; on section it was solid throughout, and presented in parts a more or less gelatinous appearance, the main portion being, however, of a somewhat firmer consistence, and a pale-yellowish color; it was everywhere intersected by fibrous septa; from the gelatinous portions long strings of mucous fluid could be drawn out, and the yellowish portions presented for the most part the naked-eye appearance of fat; here and there distinct plates, small in size, of cartilaginous tissue, were cut into. In addition to the main tumour, there were two or three similar, but quite small masses, attached to different parts of the abdomen, and the appendices epiploicæ were in many places greatly hypertrophied, and apparently converted into mucous tissue. The right kidney was at first nowhere apparent, but it was subsequently discovered incorporated with the tumour, being buried to the depth of about an inch and a half; its structure, though somewhat distorted, was distinctly recognizable. The left kidney weighed 4½ oz.: it was about normal size, capsule adherent, and cortex a little fatty, but appeared essentially healthy. The spleen weighed 8½ oz.; enlarged, soft, and pulpy. The liver weighed 32 oz.; anterior margin flattened, as above described; substance slightly fatty. The gall-bladder contained eleven irregularly-shaped calculi, each about the size of a small marble; and a similar one was found impacted in the cystic duct. The uterus weighed 2 oz.; it was somewhat enlarged and retroflected. The ovaries were healthy. The tumour in all probability originated from the retroperitoneal tissue around the right kidney. A microscopical examination was made after partial hardening in bichromate of ammonia; sections obtained on the ether-freezing microtome showed well its intimate structure; delicate fibrous bands ran in all directions, and it contained in abundance the peculiar branched cells so characteristic of myxomatous tumours; sections obtained from the parts which to the naked eye had a gelatinous appearance were chiefly made up of these cells, though in almost all fields one or more of these cells could be found somewhat distended with fat, but in sections obtained from the parts which to the naked eye looked like fat, the fatty infiltration of the myxoma cells had gone on to an extreme degree, the section resembling that of a fatty tumour; these fat globules were remarkable for their large size; the tumour was very vascular, being everywhere permeated with large thin-walled capillaries. The tumour was therefore primarily a myxoma, which had undergone lipomatous degeneration; myxomata, as is well known, being very apt to take on this change.

I am acquainted with only three instances of large abdominal tumours of this nature recorded in medical literature. Two of these are related by Dr. Homans, of Boston, U.S.A., in which operative interference was resorted to with fatal results; the second of these two cases is indeed described as a pure lipoma, but taking into consideration the structure of the tumour above detailed, it seems legitimate to inquire whether it might not have been myxomatous in its primary nature. I am indebted to Dr. Homans' paper for a reference to a case brought before the London Pathological Society in February, 1868, by Mr. Cooper Forster. The tumour in this instance was described as fibro-fatty, but inasmuch as it contained "great numbers of irregular caudate nucleated cells," between which and true fat cells all stages of gradation were met with, it was probably of a nature essentially similar to the case above recorded. In Dr. Homans' two cases, and in my own case, the tumours clearly originated behind the peritoneum;

in Mr. Cooper Forster's case this point was unavoidably left undetermined.

Some considerations of importance present themselves in connection with these cases.

1. *As regards diagnosis.*—The tumour in the case here described was looked upon during life as being ovarian; so perfectly indeed did it resemble this that this view was unquestioned by all who saw the case, nor am I acquainted with any sign by which it could have been with certainty distinguished by physical examination alone. For reasons into which it is unnecessary here to enter, no operative interference of any kind was resorted to, and an opportunity was therefore afforded of witnessing the natural course of the growth which proved fatal by simple pressure. Paracentesis was not performed; had it been attempted the result would have necessarily modified the diagnosis. It was not, however, withheld from any doubt being entertained as to the presence of fluid, for the perfect fluctuation wave observed did not appear to leave room for any uncertainty in this respect, and this is a point to which it is necessary to direct special attention. In all the recorded cases the fluctuation wave has been perfect; this fact conveys a caution to those surgeons who are in the habit of operating upon ovarian tumours without previous paracentesis, for I do not believe that in women (and three out of the four cases occurred in women) these tumours can be certainly differentiated from ovarian, except by this means.

2. *With respect to treatment.*—The profession is indebted to the boldness and operative skill of Dr. Homans for a practical demonstration of the possibility of removing these tumours. The results obtained are not, however, encouraging. In my own case the very numerous and intricate adhesions must have rendered a successful operation quite impracticable, even had it been possible to remove the tumour, which I do not at all believe. And a similar view is suggested by a perusal of the account of the post-mortem examination in Mr. Cooper Forster's case. If therefore operative interference is to be undertaken with any hope of success, it must be resorted to at a comparatively early stage in the development of the growth.

ON A CASE OF SUTURE OF THE MUSCULO-SPIRAL NERVE FIVE MONTHS AFTER ITS COMPLETE DIVISION,

WITH ULTIMATE RESTORATION OF ITS FUNCTIONS.

By T. HOLMES,

Surgeon to St. George's Hospital.

CASES of suture of divided nerves are not yet so common as to be of no special interest, and more particularly when they show any point on which our experience is defective. The one which is here related is chiefly remarkable for the long period which elapsed before any decisive symptom of amendment ensued, as well as for the complete restoration of function ultimately obtained.

C. J. S—, an intelligent man, aged thirty, was admitted into St. George's Hospital on Feb. 23rd, 1881, on account of paralysis of the right wrist, the result of a wound received five months previously in falling through a skylight, for which he was treated at the Royal Free Hospital. He said that for a week after the accident he had entirely lost sensation in the forearm and hand, but this partly returned at that period, and had since remained in the same condition. On his admission there was the scar of an extensive irregular wound on the outer side of the back of the elbow.

(15)

The hand dropped completely when held with the palm downwards. He could pronate and supinate the forearm freely, with the elbow flexed, but could not extend the wrist or fingers in the slightest degree, and supination was impossible in the extended position of the forearm. There was decided loss of temperature over the outer aspect of the forearm, and sensibility had diminished in the same situation, as well as over the back of the wrist and hand. He complained of no pain in the arm, but there was a tender spot at the extreme end of the scar, just external to the biceps tendon and about three inches from its insertion. The limb was much wasted, the forearm being at its widest part nearly one inch less in circumference than its fellow. The electrical reaction of the muscles was not tested. On March 10th, 1881, the operation of suturing the nerve was performed. Esmarch's bandage having been applied, the lower end of the nerve was easily found under the scar; the upper one which seemed to have retracted, was discovered by a little dissection. It terminated in a large bulb, larger than a common pea; the other end was somewhat atrophied. The two ends were rather more than an inch apart. A little was taken off the lower end of the nerve, so as to refresh it, and a portion (but not the whole) of the bulbous upper end was removed. Then, on extending the limb, it was found possible to draw the ends of the nerve together, and a catgut suture was put through the sheath on one side and a suture of fine silk on the other, avoiding the nerve-fibres as far as possible. Examination of the portion removed from the bulbous end showed marked increase of endoneurial connective tissue pressing upon and constricting the nerve fibres, and atrophy of some of the latter; no fatty degeneration. The operation was performed antiseptically, and the wound united by first intention. On March 14th it is noted, "There is a tingling sensation experienced in the arm, localized to no particular area," and on March 15th, "There certainly seems to be some power of extension returning, for with the wrist held tight to the splint he can make slight movements of extension of the fingers." A few days later it was thought that the sensation at the back of the hand was more perfect. This, however, was dubious. He then left the hospital at his own wish, and nothing more was heard of him till March, 1883, two years after the operation, when he returned to show how completely he had recovered. There is now no perceptible difference between the two arms, though perhaps the affected arm (the right) is somewhat less muscular than it would naturally be. Sensation, however, is perfect, and all the movements of extension of the wrist and fingers are performed as well on one side as the other. He says that it was about a year before the improvement was very obvious to him; but then it began to amend rapidly, and now he uses the limb as well and easily as before the accident.

Remarks.—There have been now many cases published in which the operation of uniting the divided ends of large nerves has been practiced both immediately and at considerable intervals after their division. The case which most impressed the minds of surgeons, and which brought this operation prominently before the profession, was Mr. Wheelhouse's¹ in which a man was admitted into hospital on account of paralysis of the lower limb nine months after section of the great sciatic nerve. He was placed under Mr. Wheelhouse's care with a view to amputation, so completely useless was the limb; but regained the use

¹ See Mr. Favells' Address in Surgery, Brit. Med. Jour., Aug. 5th, 1876.

of his leg after the suture of the divided ends of the nerve. This man, as I understand from notes of his case which Mr. Wheelhouse has kindly sent me, was discharged from the hospital three months after his admission with slight but obvious symptoms of returning motion and sensation, and was able to return to work as an agricultural laborer in four months from that period, or rather more than half a year after the operation. He was again seen nearly two years after his first admission, when there was still some remnant of his injury, the leg being colder, the foot more extended, the limb rather smaller, and one of the toes ulcerated in consequence of its extended position. Ultimately this toe was amputated and an instrument applied to remedy the position of the foot, and when last seen he was in Mr. Wheelhouse's words "cured and able to do anything." This brilliant success led to the adoption of the operation in many similar cases with varying success; and also led to the practice of uniting the divided ends of nerves in recent wounds.² The latter class of cases, however, differs in many respects from those of old injury, for it is a matter of constant experience that nerves may regain their function, not only after complete division, but even after resection of considerable portions of their entire trunk. The trunk of the nerve in these cases is reproduced by a process which has been completely studied experimentally. Dr. Brown-Séquard³ exhibited to the Société de Biologie at Paris the hind limb of a monkey, "on which in two months and twelve days nearly the whole extent of the sciatic and tibial nerves had been reproduced after an excision of twelve centimetres (4½ in.). The motor and sensory functions had not yet returned." It is therefore impossible to say in any case of recovery of function after immediate suture whether the same result would not have followed had no suture been used.

Is the case of old injury and persistent loss of function really different? In other words, in such a case as Mr. Wheelhouse's, where the parts supplied by the divided nerve have been paralyzed for a long period, will they recover if left to themselves? That they do so in some cases I think certain. I perfectly remember the case of a police constable who, in the year 1866, received several stab-wounds, one of which severed the musculo-spiral nerve. He was treated for the direct effects of his injuries in Guy's Hospital by Mr. Birkett, but was under my observation for a considerable period afterwards, being employed at the Metropolitan Police Office in some light work. For a long time the hand and wrist dropped, and the extensor tendons were replaced by an apparatus of elastic bands. But slowly and after a long period of total paralysis the functions of the limb returned, and I have ascertained that the restoration of function is now complete. The man was not able to dispense with the apparatus for two years and a half, and it was about two years before any trace of improvement commenced. Now, however, both motion and sensation have so entirely returned that the arm is almost as strong as the other, and the only thing he complains of is that he feels the cold more in that arm. In that case, however, Mr. Birkett, who had charge of the case and, I believe, reported it in *THE LANCET* about that date, believed that the whole trunk of the nerve had not been severed, and such a partial injury would of course be more favorably situated for repair than one in which the severed ends of

the nerve are separated by a considerable interval as in my case. Dr. Brown-Séquard's experiment shows no doubt the theoretical possibility of the regeneration of a large extent of nerve in animals after excision, and some of the cases in which the functions of a nerve have been regained after excision of a portion of its trunk on account of neuralgia prove that the same result may occur in man. Yet we must allow that such a favorable issue is highly dubious, and in a case like that under consideration, in which a long period has elapsed, and where the upper end of the divided nerve is quite separate from the lower, and its nervous filaments are included in a large bulb of fibrous tissue, any restoration of its anatomical continuity appears hopeless.⁴

I have recently had the opportunity of consulting the Jacksonian Prize Essay by Mr. Bowlby on *Injuries of Nerves*. As this essay is not yet published (though it is, of course, accessible to the members of the College), I will not take the liberty of quoting from it, but I may say that Mr. Bowlby thinks that after the atrophy and subsequent regeneration of the filaments of the distal end of the nerve, which we know to take place as a consequence of their separation from the proximal end, there ensues in unfavorable cases a secondary atrophy. If the parts of the nerve be reunited before this secondary atrophy has set in, the operation will probably succeed, but not in the opposite case. This view is both ingenious and probable, and lends much force to the doctrine that in any case in which the symptoms of paralysis are persistent after complete division of a nerve its pieces should be sought for and reunited at the earliest possible period. The fact that spontaneous recovery does sometimes occur after a long period of total loss of function, though indubitable—as in the striking instance above related—is not to my mind any argument against this doctrine, for recovery is very uncertain without operation, while after suture it is both more probable and more speedy. At least such seems the result of our present experience.

I am not able to point to any statistical collections of cases which are really of any great value, for the total number of published cases of secondary suture is not large, and an equally large, or probably still larger, number are unpublished. Thus, in the article on *Nerve Suture* by Tillmanns, in a recent volume of Langenbeck's *Archiv*,⁵ thirteen cases of secondary suture are tabulated. Of these I should class eight as successful, three as dubious, and two as failures. But in two at least of the successful cases the success, though as much as could be hoped for, considering the time after operation, was not yet perfect. On the other hand, the three dubious cases were reported too soon after the operation to be classed as unsuccessful. Tillmanns' collection, however, is evidently imperfect, for he makes no mention of Mr. Wheelhouse's operation, which is the leading case in

² An interesting paper On the Immediate Suture of Divided Nerves, by Mr. H. Page, will be found in the *Brit. Med. Jour.*, May 7th, 1881.

³ *Comptes Rendus de la Soc. de Biol. de Paris*, 1882, p. 30. *System of Surgery*, 3rd Edition, Vol. ii., p. 214.

⁴ Dr. Weir Mitchell says: "The future of cases of entire severance of nerves will depend on the amount of nerve cut away, the sequent neuritis, and the fate of the surrounding tissues; but even when the portion lost has been an inch or more, we should not absolutely despair of a large return of function, when we remember the extraordinary regeneration of nerves after excisions for neuralgia." *Injuries of Nerves*, p. 226. This observation, however, and those which follow it as to the results of treatment refer to a period very soon after the accident, not to the prognosis and treatment of old injuries. And Dr. Mitchell's remarks on nerve suture also apply only to the immediate treatment of wounds. Mr. Page says, and I have no doubt with truth (after a proper distinction between clean cuts and lacerated wounds) that "the usual history of divided nerves in lacerated wounds has been one which has not told us of repair and of restored function, but rather of abolished function, neuralgia, and the many disturbances of nutrition to which such nerve lesions give rise."

⁵ *Ueber Nervenverletzungen und Nervenheft*, *Archiv f. Klin. Chir.*, 1882, vol. xxvii., p. 1.

this country, and, though not the first operation of its kind, was, I believe, original, as far as Mr. Wheelhouse was concerned, and first called the attention of English surgeons to the subject. Mr. Bowlby's paper contains references to twenty cases of secondary suture, with a much larger proportion of failures, in fact, I believe only six are classed as perfectly successful; but then Mr. Bowlby observes, what is a fatal objection to the value of the statistics of this operation hitherto, that in many of the most successful cases, as in mine above related, the success has been so long delayed that accounts which are published only a few weeks after operation are quite worthless. Thus, in a patient of Mr. Pick, on whom an operation very similar to the one above reported was performed on the musculo-spiral nerve, the operation was thought to have failed, and the lad was discharged, apparently with no benefit. Through the kindness of Mr. Coltart, of Epsom, we have lately ascertained that he has now, like my patient, entirely recovered. Mr. Pick may possibly record the case.

With regard to the time after the injury at which the operation should be undertaken, we are not yet in a position to lay down any certain rules. Obviously, if the parts are quite quiet and the wound completely healed, there can be no motive for deferring the operation, and both the theoretical considerations insisted on by Mr. Bowlby and the practical experience of cases warn us against too long delay. Yet a case is on record in which Mr. Jessop⁶ operated on the ulnar nerve with at any rate partial success nine years after its division. I lately united the median and ulnar nerves eight days after the accident, and was led to suspect that it would have been better to have waited till all inflammation in the wound had passed over, or even till the wound had entirely united; but the case is not yet complete, and further experience is wanted on this head. One thing I think we are justified in saying—viz., that there has been no instance hitherto recorded of any harm from the operation—no tetanus or acute neuritis—and this consideration adds force to the rule now, I believe, generally adopted to unite by suture the ends of all nerves which are seen divided in recent wounds.

A question is often raised in this operation as to the method of passing the sutures, whether through the tissue of the nerve itself or through the sheath only. I think all that we need say on this head is that the sutures should have a firm hold; whether they be passed through the thickness of the nerve or not seems of little consequence. In only one of the thirteen cases above referred to as quoted by Tillmanns was the precaution taken of including only the sheath in the suture. The material of the suture is probably a matter of some importance. Catgut is unirritating, but is not sure to hold beyond a few days, so that it seems a good plan to reinforce the catgut suture with one or two of fine silk (as in my case) or horse-hair. It does not seem necessary to remove more than a very small portion of either end of the nerve. In the above instance I purposely took away very little, in order to obviate tension as much as possible. Had the separation between the cut ends been less, I should have liked to excise the whole of the bulb on the upper, and all the wasted part of the lower, end; but I thought it better under the circumstances to remove very little, and the result justified the course adopted.

THREE CASES OF SUCCESSFUL REMOVAL OF TRACHEOTOMY TUBES.

By HENRY SMITH, M.B. Lond., S. Sci. Cert. Camb.

AMONG the legacies bequeathed by house-surgeons to their successors, it is no uncommon thing to find a child on whom tracheotomy has been performed for temporary laryngeal obstruction, and who beyond wearing a tube is otherwise well. It was my fortune to inherit three such cases on my appointment as house-surgeon to the Children's Hospital, Great Ormond-street, and for permission to publish them I am indebted to the kindness of Mr. Thomas Smith and Mr. Howard Marsh, under whose supervision and with whose approval the treatment adopted was carried out.

CASE 1.—William P—, aged thirteen months, was admitted to the Children's Hospital with diphtheria, and tracheotomy performed on Sept. 27th, 1880. In June, 1882, he was still wearing an indiarubber tube, and, though now able to do without it for hours together in the daytime, he had never slept without it since the operation. He could run about the ward without dyspnoea; his general health was fairly good, though he suffered from cough with copious expectoration of mucopus through the tube. Voice good; occasional sickness. On the evening of July 7th, 1882, the tube, having been out since the morning, was not replaced.—July 8th: Has passed a restless night, with noisy breathing and well-marked recession of the lower ribs.—10th: The tube, which had been out since the 7th inst., was replaced, as the child looked pale and languid, owing to broken rest. The little fellow, who was a general favorite in the hospital, had not hitherto been restricted in his diet either as to quantity or quality, and his occasional vomiting could generally be accounted for by some indiscretion of this kind. He was now put upon a plain diet and all indigestible food withheld, with the result that when the tube was left out on the 26th July no further occasion arose for its being used again. At first the opening into the trachea was covered with a piece of strapping, but as this could not easily be kept in place, a small pad of cotton-wool covered with gauze was substituted for it, and answered the purpose better. The boy's health improved very much—he became livelier, lost his cough, and his voice grew stronger, before he was transferred on Aug. 31st to the Convalescent Home at Highgate. When seen on February 22nd, 1883, he was very well, but an opening large enough to just admit a small probe was left in the trachea.

CASE 2.—William M—, aged four years, came under Mr. Marsh's care at the Children's Hospital on June 6th, 1882, wearing a silver tracheotomy tube. The operation was performed for laryngeal spasm on March 30th, 1881, at the Westminster Hospital, where several attempts had been made to get rid of the tube. On admission to the Children's Hospital he was well nourished and in fair health, but was troubled with cough and free expectoration of thick stringy mucopus. The tube was changed night and morning with considerable difficulty; for, objecting to be interfered with, he invariably worked himself into a passion, and struggled so violently that he had to be held down while it was being done. At these times he suffered from marked dyspnoea, clearly brought on by his own ill temper. Mr. Marsh, pointing out the injury likely to result to the delicate mucous membrane of the trachea from the constant pressure of a silver tube, told me to substitute an indiarubber one as soon as possible; so on June 20th, when the child had been got more under control, a Baker's tube was used; this he

⁶Tillmanns, op. cit., Case 11, Brit. Med. Journ., December 2nd, 1871.

liked better than the silver one, and resisted its changing much less. After removing it on the morning of June 27th, and noticing that he breathed quite comfortably, I determined to leave it out; but this not meeting with the boy's approval, he threw himself into a rage, and tossed himself about until he had brought on such urgent dyspnoea that it required some firmness to resist the temptation to replace the tube, which he called for; however, he was made to understand that it would not be put in, so after awhile he gave in and quieted down. He next refused to eat his dinner, saying he should choke without the tube, but a good appetite, with a little persuasion, furnished the best argument against this. He was kept quiet in bed and strictly watched. He went on with little difficulty of breathing until the evening, by which time the tracheal opening by contraction and puckering of the skin had become all but occluded. On falling asleep the dyspnoea became very great, and was accompanied by such recession of the ribs, that had he been suffering from acute laryngeal obstruction his trachea would certainly have been opened. On waking up, however, he breathed easily again. He was accordingly awakened at intervals, and so he passed the night. Every precaution was taken for dilating the opening at a moment's notice, should it have been thought absolutely necessary. The next day, though rather exhausted, the little fellow felt pleased at having gone a night without his tube, and refused to have it again when its reintroduction was suggested to him. The next night he slept right on without having to be roused, and continued to improve so that no further need arose of resorting to the tube. His cough left him and the wound closed. He left the hospital on August 3rd, for the Convalescent Home at Highgate, well. For some time after the tube was removed the breathing, during sleep, both in this case and the one above, was of a noisy, snoring character, but never stridulous.

CASE 3.—Frank S—, aged four years and five months, was admitted to the Hospital for Sick Children for diphtheria and tracheotomy performed on April 11th, 1882. In June he was still wearing a Baker's tube, as he had been liable to sudden attacks of dyspnoea if it were left out. These were supposed to be due to granulations in the trachea, as bleeding occurred each time the tube was changed. He suffered from bronchial catarrh and coughed up thick mucus through the tube. Voice good. On June 23rd an attempt to dispense with the tube, by gradually shortening it, was begun at Mr. Marsh's suggestion, with the result that no more bleeding occurred, but when the tube was about three-quarters of an inch long the breathing was worse than before. This was due, perhaps, partly to the end of the tube being against the posterior wall of the trachea, and partly to the fact that the child had caught cold and was then suffering from general pulmonary catarrh, as a longer tube did not relieve the dyspnoea entirely. On June 29th the tube was finally removed, the boy having gained confidence from seeing that his neighbor (Case 2) had got rid of his, and by the next day the wound had closed. On July 13th the patient was discharged well. This case differs from the other two chiefly in the much shorter time he had worn a tube and in its final removal being free from difficulty.

The importance of dispensing with the tube in cases of tracheotomy performed for temporary laryngeal obstruction as soon after that obstruction is removed as possible is generally admitted, because, apart from the inconvenience of wearing a tube and the actual injury it may do to the trachea, there is always danger in trusting these

cases, if children, to the care of friends, for should the tube become dislocated and a sudden attack of dyspnoea come on, a child would naturally be afraid and struggle, while his friends, alarmed, would stand helplessly by perhaps, or fail to replace the tube in time to save the child's life. Such a case has been known to occur. Again, the chronic bronchial catarrh which, I believe, is invariably present so long as the tube is worn, and which is probably due largely to breathing air not previously filtered, as it were, through the nose and mouth, as normally, is another reason for restoring the natural mode of breathing. One difficulty in the early treatment of these cases is the fear children have when the tube is taken out. So long as it is in they breathe without any trouble, but when out they have to make an effort they are not used to, and frequently, too, spasm comes on and they grow alarmed; but by leaving out the tube often, even for a minute or two, and by gaining the confidence of the children in other ways, this difficulty is generally soon removed. During the last ten months at the Children's Hospital in only two of seven successful cases of tracheotomy for diphtheria had I any great difficulty in the removal of the tube, and these yielded to importunity.

In a paper in vol. xlviii., p. 227, of the Medico-Chirurgical Society's Transactions, Mr. Smith has shown that tracheotomy, whether performed for diphtheria or acute laryngitis, "is liable to cause undue irritability and disorderly action of the muscles of the glottis, and to interrupt their usual rhythm," and that "perhaps this is the effect of the enforced cessation of all exercise of function in the larynx which the operation entails;" and in explanation of those cases where the tube can be dispensed with, except during sleep, he suggests that "the influence of the will may be necessary to regulate and secure the due action of these muscles, the perfection of whose movements has been impaired, and that on this account inspiration through the larynx during sleep is impossible." Considering, then, these things, may we not hope to restore to their normal involuntary character the impaired functions of the disused laryngeal muscles by letting them strive with the difficulty during sleep; in other words, by exercise, though their first efforts may be disorderly and clumsy, as in the cases given above?

CONDENSED MILK AS FOOD FOR INFANTS.

By F. DAWTREY DREWITT, M.A. M.D.,

Assistant Physician to the Victoria Hospital for Children, and to the West London Hospital, etc.

A TRUE Englishman's natural dislike of everything which has even the appearance of being unnecessarily artificial has caused a good deal of prejudice against condensed milk, and just now there seems to be such a marked exacerbation of that prejudice that a very valuable modern discovery is in danger of falling into disrepute. Everyone who has had anything to do with the crowds of sickly, ill-fed children with which London abounds must be aware that not only during the prevalence of that most fatal illness, summer diarrhoea, but through every month in the year, a large amount of infantile life is continually being saved by its use, and it would be a matter for regret if condensed milk should be condemned by those who have not yet attempted to give it a fair trial. The commonest objection to it is that it is too sweet. Of course it is very sweet; and in spite of our instinctive liking for sweet things, whether ripe fruit or raisins, chocolate or sugar-plums, an instinct

which is so marked in childhood, few persons would think of giving a baby condensed milk when the mother had milk enough of her own, and was able to suckle the child. But, on the other hand, cow's milk is not sweet enough, and when compared with human milk is very indigestible. It can only be made at all a possible food for babies by adding to it sugar and water and so making it more like condensed milk, but even then it is not so digestible as condensed milk; and it is not difficult to see the reason. Place some cow's milk with its added sugar and water in a wineglass, mix in another glass some condensed milk with water till it has, as far as one can judge by eye, about the same consistence and opacity; stand the two glasses side by side, and add to each, as the stomach does, a few drops of dilute nitrohydrochloric acid and watch the result. They both curdle, but the curd formed in the wineglass of condensed milk is distinctly more friable, more mixed with the watery part than the curd in the cow's milk, and after standing for some time this is still more evident, for the curd in the fresh milk separates completely from the fluid into a firm clot, while in the condensed milk it remains more granular, more broken up, and more mixed with the fluid. And, except among the very poor, who cannot afford to buy cow's milk, it is this hard clot of cow's milk which is more than anything else the *fons et origo* of that only too well-known incessant cry of dyspeptic hand-fed babies, and of all the vomiting and diarrhoea which so often carry them off—that hard indigestible clot, of which there is so little in human milk, and of which the analytical reports say with precise truth, as they might of a dinner of cheese, that it is so “nutritious,” so full of “nitrogenous matter.” And it is actually because of the small proportion of clot or casein which condensed milk contains that the second objection to it is made by the analysts. This clot or casein, which is so much the bane of hand-fed infants that the addition of oatmeal-water or gruel to cow's milk, even before the child is able to digest any starchy food at all, often makes the milk more digestible, for the simple reason that the suspended particles in the oatmeal-water are interspersed through the coagulum which is formed when the milk enters the stomach, and so help to make it soft and friable, just as water-weeds frozen into ice make the ice brittle and dangerous to skate on.

Condensed milk, of course, varies in quality, and it is important not to use any of the common cheap kinds. Of those which are generally seen in the shop windows, the out-patient mothers at our children's hospitals generally prefer the original Anglo-Swiss milk, the “one with the milkmaid on the tin,” as they call it, and it seems to me as good as any. And lately some unsweetened Swiss milk has been prepared, which has the appearance of being good, and certainly deserves a trial.

Then as to condensed milk causing rickets, I can only say that I found it very difficult to trace rickets to condensed milk properly given. Most hand-fed children are delicate, a very large proportion die, and a still larger proportion have some tendency to rickets. Oatmeal and other gruels seem to be directly concerned in bringing it about; but though I have seen very many children who have had to change their diet to condensed milk, I have seen none who have thereupon become rickety. One case I do remember among the out-patients at the Victoria Hospital for Children of a child a year old who had advanced rickets. It had been fed on condensed milk, the mother said, from birth, and yet it had never thriven. She had done her best for the child; the milk was of the best brand, and she never spared

it. She spread it thick on slices of bread, and gave it to the child whenever it cried. “and yet,” the poor woman said, “the child doesn't get on.” That condensed milk given in that form to babies, even without the bread, may cause rickets I do not attempt to deny. It appears to me to be rather to the credit of condensed milk that the baby survived.

Everything depends upon how condensed milk is given. It ought to be diluted with ten or twelve times its bulk of water, or with more than that if the child is thirsty; and if any tendency to sickness remains, about one-sixth of the water ought to be lime-water, which still further neutralizes the action of the acid of the stomach and delays the formation of the clot. The water should be boiling when added to the milk, especially in the summer. It gets rid of the infusoria in bad water or in a long-opened tin. Once a day a teaspoonful of Mellin's food may be given with the milk. It is one of the best of the semi-digested foods, and children like it. With such a diet infants who at once vomit cow's milk, who keep their knees drawn up in pain, who are wasted and wretched looking, or in danger of dying from diarrhoea, become contented and happy, rapidly gain flesh, and are able after a time to begin a little weak cow's milk and water or whey. And it is thus as a bridge across a bad time that I consider condensed milk to be of the greatest importance; but the bridge may extend over some months, and in the mean time the irritability of the intestinal tract subsides, and other forms of nourishment can be gradually administered.

Three or four years ago when I was a resident medical officer at the Children's Hospital in Great Ormond-street, where good cow's milk could always be procured, and where it was given with care and discretion, condensed milk formed nevertheless a valuable article of diet, and was and probably is still used in all the medical wards; but among the poor in their own homes, where the milk is often bad throughout the year, and sour for at least three months of it, condensed milk is simply an inestimable boon.

Brook-street, W.

AN OPERATION FOR THE RADICAL CURE OF FEMORAL HERNIA.

By WALTER H. BROWN, M.R.C.S.,

Surgeon to the Leeds Public Dispensary; Demonstrator of Anatomy, Leeds School of Medicine; Late House-Surgeon, Leeds General Infirmary.

A FEMALE, aged sixty, had for years been troubled with a large femoral hernia. Many varieties of truss had been tried, but all failed to afford relief, and the hernia has been strangulated two or three times for short periods. For reasons which I will give below I deemed it desirable to make an attempt to effect a radical cure, to which end I performed the following operation.

I made an incision as for strangulated bowel, and opened the sac. I reduced the bowel, and then found that the crural ring was large enough to admit three fingers; lying at the posterior part of the sac was a large portion of omentum, which was adherent to the sac, and, as in separating these adhesions the omentum was freely handled, I removed the portion which had been in the sac, and tied the stump with a stout silk ligature, leaving the end of the ligature long. I then dissected out the sac, and, after ligaturing the neck, removed the entire sac. I had next a large piece of omentum removed by a ligature within the abdominal cavity just opposite the cru-

ral ring, the ligature being brought out through a small opening I had made in the peritoneum close to the ligatured neck of the sac. It now occurred to me that I might use this omentum as a plug to close the crural ring. I therefore drew the omentum down until it was in contact with the neck of the sac, and found that it remained in its new position without much tension. I thus had the ligatured neck of the sac and the ligatured stump of the omentum to resist the return of the hernia. The wound was closed in the ordinary way, the two silk ligatures being brought out at the lower end.

It is unnecessary to give further details of the progress of the case as the woman made a good recovery. There was no disturbance of temperature, the wound healed by first intention save at the point through which the ligatures came; the ligature on the neck of the sac came away on the tenth day, but the one on the omentum remaining firm at the end of the sixteenth day, it was cut short and the wound healed in two days.

The operation was performed in accordance with Professor Lister's system of antiseptics, and the wound dressed with salicylic silk as introduced by Mr. McGill, of Leeds. It is now five months since the operation, and the result so far has been perfectly satisfactory. There is no hernia, the woman is enabled to perform her household and other duties in comfort; she wears a pad similar to that of an ordinary truss over the scar in order to support the necessarily weak ring. I am fully aware that an operation such as I have described is open to criticism, and I therefore wish before closing to draw attention to my reasons for operating. First, the patient being weary and discomfited by her ailment was willing to accept the risk of operation and possible failure after they had been fully explained. Secondly, a fair trial had been given to mechanical support, and the results had been entirely unsuccessful. Thirdly, I deemed it right to attempt a cure by operation, bearing in mind the fact that of late we have been in the habit of dealing more freely with cases which involve interference with the peritoneum. The brilliant results obtained by Mr. Banks, of Liverpool, and Mr. Spanton, of Hanley, in dealing with inguinal herniæ, led me to undertake the operation just described, and Mr. Spence, of York, has performed a similar operation with like success.

Of course the number of cases in which one would operate would be limited to those in which mechanical support had failed to give relief.

Leeds.

COMPLETE SUPPRESSION OF SALIVA AFTER MUMPS.

By A. St. C. Buxton.

COMPLETE suppression of saliva in both parotids and both submaxillaries is of extremely rare occurrence. A case has, however, quite recently come under my care, the features of which were as follows.

A lady of over middle age, while in the country, contracted mumps. As soon as the acute inflammation of the salivary glands had subsided, and all pain and swelling had disappeared, she returned to town, and I was called in to see her. She spoke with great difficulty, and was forced to sip water at very short intervals in order to be able to speak at all. She told me that ever since the pain in the parotids and submaxillaries had vanished her mouth had remained persistently quite dry.

On examination I found her tongue, gums, cheeks, palate, and pharynx—in fact as much as it was possible to see of the mouth and throat—in a fearfully dried up state. The tongue was thickly coated with a tough brown fur, which was horn-like. So hard was it that on striking it gently with a metal probe a distinct sound as of tapping the cover of a book with a cedar pencil was produced. The rest of the interior of the mouth was also extremely hard, and she experienced great stiffness in opening and closing the jaws. No swelling or tenderness on pressure existed about the salivary glands, and the orifices of Stenson's and Wharton's ducts were plainly seen. It is needless to say that she retained no sense of taste. She complained of the heat felt in the mouth, but the temperature was quite normal. Her sleep was greatly disturbed at night, and she awoke at short intervals with the most intense longing for cold water; but drinking afforded no relief. It is worthy of notice that for some three or four years she has been affected with paralysis agitans, both limbs of the right side being very shaky. She enjoys otherwise excellent general health, and, notwithstanding the trembling in the right leg, is able to walk well, and takes plenty of exercise out of doors. There was a great deal of difficulty in feeding her, for she absolutely refused milk and beef-tea, and the effort necessary to swallow jelly and other semi-solid food was very great. I prescribed gargles of potassic chlorate, and ordered glycerine to be applied locally to the interior of the mouth and surface of the tongue. I ordered also an infusion of fifty grains of jaborandi to be taken daily for four days. Although the glycerine afforded some slight relief to the mouth by its mechanical effect as a lubricator, there was positively no effect produced on the salivary glands. Copious perspiration (from the jaborandi) took place, and left her feeling very weak. I therefore abandoned that drug, and substituted mercuric iodide dissolved in excess of potassic iodide. I gave large doses for ten days with no result beyond the production of a feeling of malaise. It was evident that something must be done soon to excite the flow of saliva, for the patient had been in this condition for nearly three weeks, and was in the lowest depths of despair and misery. The next step which I took therefore was the application of a continuous current of electricity generated by a 30-cell battery (pint cells) of the Leclanché type. I introduced a very fine silver probe into Stenson's duct on one side, and pushed it gently on until I met with obstinate resistance to further entrance. The probe had then entered the duct about an inch. My assistant held the positive electrode firmly to the nape of the neck, while I cautiously applied the negative pole to the free end of the probe. I instantly noticed a contraction of the fibres of the buccinator, but as no pain resulted I fixed the wire to the probe and allowed the passage of the current to continue for ten minutes. While the probe was in the duct a thick white liquid oozed from the orifice. It looked something like pus. On removal of the probe a single drop of clear saliva followed it. Thinking that it was just within the bounds of possibility that a small abscess had existed somewhere about the duct and had been overlooked, and the probe had simply opened it and so cleared the obstruction to the flow of saliva into the mouth, I determined to thoroughly explore the other Stenson's duct and both Wharton's ducts before applying the current again. I passed the probe into all three remaining ducts as far as possible, removed it, compressed and squeezed the parts, but no pus followed. I repeated this again, but without finding a trace of pus. I then applied the current as before, with

precisely the same result as in the first instance. I had the satisfaction of seeing four drops of saliva, one at the orifice of each duct. I visited my patient an hour afterwards, and a gentle flow of saliva was discernible from each duct. For three days the quantity steadily increased, without any further use of the current, and at the end of that time almost the normal amount was being poured out. The mucous membrane lining the mouth and the tongue was rapidly resuming its natural appearance. I have not seen my patient since, but I received a letter two days later stating that she had greatly improved; that the tongue was feeling quite comfortable, and that she was able to taste. A somewhat similar case is mentioned in the *London Medical Record*, 1877. The suppression of saliva resulted on that occasion from tonsillitis, and the flow was restored by stimulation by continuous current "frequently reversed." I did not reverse my current, preferring to submit the glands to the continued action of the negative pole. I find no mention of the condition in any medical work in which I have searched, including Quain's Dictionary of Medicine.

The Grove, W.

ON A CASE OF LABIO-GLOSSO-PHARYNGEAL PARALYSIS OCCURRING AT THE AGE OF TWENTY-THREE YEARS.

By A. CHAMPNEYS CLARKE, L.K.Q.C.P.I., etc.,

On November 13th, 1882, I was sent for to see Mrs. B—, aged twenty-three years, the wife of a coal miner. I was informed that she had always enjoyed good health, had borne one healthy child, and was now six months advanced in pregnancy. The previous evening, while shoveling coals into the coal-house, standing at the time in the snow, she had been seized with what was described as a sort of stroke. I found her suffering from paralysis of the left side of the face and left arm; articulation was imperfect owing to paralysis of the left half of the tongue, which when protruded was drawn towards the right side of the mouth. She gradually recovered from the facial paralysis, and in a great measure the use of her left arm, only complaining of its being weak. On Feb. 11th I was again sent for to see Mrs. B—, as she was said to have had another stroke. On arrival I found she had just been delivered of a healthy child, after a short and easy labour. She was completely unable to articulate or swallow, the tongue lay immovable on the floor of the mouth behind the teeth, hollowed in the centre; she could not close her lips completely, and the saliva dribbled from the sides of the mouth. The patient, an intelligent woman, complained (by signs) of great pain in the neck and throat, the muscles of which were contracted. She was at first fed through a tube, but disliking this means she was spoon fed, the spoon being introduced well back. She made a rapid convalescence from her confinement, and at the end of a week could swallow with considerable difficulty, placing the food (gruel and beef-tea) well back in her mouth and throwing the head back. The stiffness passed off, and she can now (March 21st) take fluid and semi-solid food fairly well. She is able to go about her household duties, but the tongue still remains paralyzed, though by a great effort she can raise it as far as the edges of the teeth. She can close the lips at will, but when not called upon to do so the mouth hangs open and the saliva dribbles from the edges. She cannot articulate a single word, nor any letter in which the tongue has to be used.

The points of interest in this case are, I believe, the hitherto unknown occurrence of glosso-pharyngeal paralysis at so early an age; its being preceded by an attack of paralysis of the left arm and left side of the face, evidently brought on by exposure to cold during great exertion; the recovery from this attack, and after a period of three months the occurrence of an altogether different disease, bulbar paralysis, at a time when she was called upon for great exertion—that is, when labour commenced; and the gradual improvement from this disease. The case is still under my care, and will be watched with a view to future report. The treatment has been small doses of strychnia with iron, and faradization.

Durham.

ON THE USE OF JABORANDI OR PILOCARPINE IN THE COLLAPSE OF SCARLATINA MALIGNA.

By ROBERT PARK, M.D., etc.,

Physician for Diseases of Women and Children at Anderson's College Dispensary, etc.

On March 3rd I was sent for to see A. S—, aged five years who had been seized suddenly, early on the morning of the previous day, with violent vomiting and purging. Nothing would "lie on his stomach," even water, the mother said. When I saw him he exhibited all the objective symptoms of collapse. He moaned occasionally, "Oh, my belly." There was also the characteristic smell which exhales from the body of many patients with enteric or scarlet fevers. In the present case diagnosis was impossible. I inclined, however, to the belief that it was a case of scarlatina maligna, the season of the year and the history putting cholera out of the question, and such a sudden onset being very unusual for enteric. Moreover, the abdomen was flaccid and flabby. Temperature in axilla 101.5°; pulse 160. I ordered half a teaspoonful of brandy every hour, and the following mixture:—Liquid extract of jaborandi, three drachms (Richardson's); solution of acetate of ammonia, two ounces; syrup of poppies, four drachms; chloroform water to four ounces. A teaspoonful every two hours.

March 4th.—This day the child was very much *in statu quo*. However, purging had ceased, though he was sick, and vomited occasionally. He had scarcely passed any water during the last twenty-four hours. Eyes half open and glazed. Temperature in flexure of thigh, 96°. Dose of jaborandi doubled, and to be given every hour. Enema of turpentine and beef-tea; milk and soup and brandy *ad libitum*. Hot mustard applications were ordered also to the calves of the legs and feet, and to the abdomen. After a few hours, there being no signs of the physiological action of the jaborandi, unless, perhaps, a slight increase of strength in pulse, I gave him a few drops of amyl nitrite to sniff. This gave a temporary flip to the heart, but he soon relapsed into a semi-comatose condition, and it seemed as if death was going to be the issue. Thoroughly satisfied, however, that jaborandi was the remedy if it could only be got into circulation, I had some fresh solution of the active principle (pilocarpine) prepared and injected hypodermically, one-thirtieth of a grain, into the inner surface of the thigh, and this failing to produce any characteristic phenomena, I injected another one-thirtieth into the arm about twenty minutes afterwards. This produced an immediate improvement in the pulse, and he became more restless, and in a short time asked to be lifted, when a copious flow of clear urine was

passed, together with a watery stool, dark brown in color. None of the characteristic phenomena of pilocarpine were produced.—5th: The child has neither vomited nor purged during the night, but has passed water. There is a slight flush on the face; no sweating; no ptialism; extremities not so cold; respiration no longer sighing; pulse 140, and of better tone; ears warm; eyes no longer glazed; and upon the whole reaction, though faint, may be said to be fairly established. Treatment continued.—6th: Reaction complete, but not excessive. Pulse 140; temperature 102°.—7th: None of the symptoms peculiar to either enteric or scarlet fevers have made their appearance, but the strong fever smell is no longer obtrusive.—10th and 11th: The pulse still keeps quick, 140; temperature from 101° to 102°. The very thick creamy fur which has completely hidden the tongue for the last two days completely exfoliated to-day (11th), and has left the tongue raw and clean, and so tender that hardly anything can be borne by it. The same thing seems also to have happened with the stomach, as the little fellow positively screams when food enters it.—12th: The child is comparatively well to-day, but his pulse still keeps to 140, and he is very weak. He has also had, in answer to a small dose of castor oil, two stools of a tarry description. The urine examined on the 15th was normal in all respects, there being neither albumen nor tube casts present.

Remarks.—This case offers some special features for consideration—namely, the completeness and prolonged duration of the collapse, the exfoliation of the gastro-intestinal mucus, and the limited duration of the entire illness (eight days). The only case at all parallel with it that I have met with was at Stewarton, Ayrshire. It occurred in a boy, about six years old, the last of a family of four to take the fever. The vomiting, purging, and collapse, however, were of short duration, and a faint rash did appear on the skin, and recovery followed. The etiology of this case is very obscure, as no scarlet fever is known of in the neighborhood, I am informed by favor of Dr. Russell. This fact, taken with that of recovery, makes me almost think it may have been an acute gastro-bilious attack, or acute gastro-intestinal catarrh; but then the sudden onset, peculiar odor, pyrexia even during collapse, suppression of urine, and desquamation of gastro-intestinal mucus, appear to negative this idea. My theory is of course that the exanthem was determined to the gastro-intestinal surface, there causing complete suspension of all alimentation and rejection of the contents of the alimentary canal, and subsequent desquamation of the mucous membrane. In fact it became an endanthem, and in this connection it may be mentioned that the winds have been unusually bitterly cold and piercing here since March came in. The urine was not examined till the 16th, when it was found to be in all respects normal, and at this date the child is slowly gaining strength, though not yet able to walk.

Glasgow.

A CASE OF POPLITEAL ANEURISM.

By WARRINGTON HAWARD, F.R.C.S.,

Surgeon to St. George's Hospital.

THE following case seems worth recording, as a contribution to the evidence bearing upon the behavior of the catgut ligature as applied to large arteries in their continuity.

R. N—, aged fifty-seven, a butler, was admitted into St. George's Hospital, under my care, on July 8th, 1882, with an aneurism of about the

size of a cricket-ball in the left popliteal space. The tumour had the characteristic expansile pulsation, which was felt most forcibly on the inner side, where also it was most prominent. It could be moved on the bone; and its pulsation stopped when pressure was made upon the femoral artery in the groin. A loud bruit was audible over the tumour. The leg was swollen and the skin oedematous. The man was of tolerably healthy appearance, excepting that the capillaries of his face were somewhat dilated. His hair was grey, his pulse rather weak, and he had a slight cough. His urine was natural; so were the heart sounds. He stated that his father had died of heart disease. He himself had been in good health until the last two years, during which he had been subject to cough. He had never had syphilis, and had never been intemperate. Six weeks before admission he felt a pain in the left knee, which was persistent; but he noticed no swelling till a month had elapsed, and then he observed an oblong pulsating swelling behind the knee. He continued, however, to walk about for another week, when the pain became so severe that he took to his bed; he had therefore been resting in bed for a week before admission, during which time the tumour was still increasing.

The limb was raised, and for ten days the leg was kept in the flexed position. For the first few days the pulsation diminished, but it was then noticed that the tumour was increasing towards the inner side. It was therefore determined to ligature the femoral artery without further delay.

On July 20th the artery was tied in Scarpa's triangle with a carbolized catgut ligature prepared with chromic acid, in the manner recommended by Mr. Lister. Antiseptic precautions were observed, but no spray used. The ligature was cut short, a small drainage-tube inserted in the wound, and the incision closed with a continuous suture of carbolized silk. The dressing consisted of a pad of salicylated wool enclosed in encalyptus gauze.—22nd: The wound had healed excepting where the drainage-tube projected. The tube and stitches were removed, and a strip of plaster was placed across the wound. There was slight pulsation to be felt in the tumour.—25th: No pulsation felt in the aneurism. No fever or constitutional disturbance ensued upon the operation; the aneurism consolidated, and, with the exception of a little cough, he was quite comfortable on Aug. 9th. He was dressed and lay outside his bed. The aneurism continued to diminish, and his condition seemed satisfactory until Aug. 19th, when in the night he became suddenly delirious; the delirium was succeeded by drowsiness, and subsequently by coma, in which condition he died on the 22nd, a month and two days after the operation.

Permission could only be obtained to examine the limb, but this gave us the opportunity of ascertaining the condition of the ligature thirty-three days after its application. A careful dissection of the aneurism and its afferent and efferent vessels was made by Mr. Ross, the curator of the museum, with the following result:—The femoral artery was filled by a firm decolorized clot, which extended from the seat of ligature to the origin of the profunda, about an inch below Poupart's ligament. The remainder of the artery below the ligature, as well as the popliteal almost to its division, was also filled with a firm partially decolorized clot. The lower part of the popliteal artery presented a fusiform dilatation of about the size of the last joint of the thumb. From the upper part of the vessel projected a globular aneurism, the size of one's fist, which communicated with the artery by an opening about three quarters of an inch in di-

ameter. The sac was formed by the outer wall of the vessel and was filled with laminated clot, the outer layers of which were decolorized. The catgut ligature appeared unchanged; it surrounded the artery, being embedded between the outer coat of the vessel and a thin layer of fibrillated lymph. The knot was firm. The two inner coats of the vessel were divided at the seat of ligature; they were curled inwards, and were united where in apposition. The external coat of the artery where surrounded by the ligature was intact. The examination showed, therefore, that the chromicized catgut ligature, thirty-three days after its application, remained firmly around the artery in a perfectly harmless condition. There was no sign of irritation in the surrounding tissues, which were soundly healed.

The cause of death I suppose to have been cerebral hæmorrhage; but this was clearly quite unconnected with the operation, from which the man had completely recovered.

Savile-row, W.

A Mirror OF HOSPITAL PRACTICE, BRITISH AND FOREIGN.

Nulla autem est alia pro certo noscendia, nisi quamplurimas et morborum et dissectionum historias, tum aliorum tum proprias collectas habere, et inter se comparare.—MORGAGNI *De Sed. et Caus. Morb.*, lib. iv. Proœmium.

KING'S COLLEGE HOSPITAL.

PARALYSIS OF THE SERRATUS MAGNUS AND RHOMBOID;
ELECTRICITY; IMPROVEMENT; REMARKS.

(Under the care of Dr. FERRIER.)

For the report of the following case we are indebted to Dr. Norman Dalton, medical registrar:—

John C—, aged forty-four, presented himself at the out-patient department of this hospital on March 29th, complaining of weakness in the right upper limb. His attention had been drawn to an undue prominence of the right shoulder blade. The following notes were taken:—The patient works in a foundry at Woolwich and occasionally has the mixing of metals, including lead, but the latter only in small quantities. He has never had colic and there is no definite blue line on the gums. As a rule he works with a hammer all day, using the right arm only. He has been a free drinker all his life, and states that he had an attack of delirium tremens six or seven years ago. With this exception he has had excellent health. He has never had syphilis or ague, and he has never suffered from neuralgic pains. About eight weeks ago, on a Sunday, he found on waking that he had completely lost the use of his right upper limb. He could not raise his hand to his mouth nor remove his arm from his side. He had gone to bed feeling quite well, and neither before nor since has his general health suffered in any way. He is quite certain that no feverishness or other general symptom preceded or accompanied the onset of the paralysis. There was no draught in his bedroom, and his position during sleep had not been in any way cramped. He had had no blow on the shoulder. Besides the loss of power he had some pain in the muscles of the right upper arm and over the shoulder blade on the same side. There was no loss of sensation in the affected

limb, and he has had no twitching of the muscles.

On the Monday his condition remained about the same, but on Tuesday he had recovered sufficiently to return to work, and use the hammer with his right arm. In about a week he had completely recovered the use of his forearm, but the limb as a whole remained weak. He noticed this particularly when he had to push before him any heavy object (e.g., a truck). His fellow-workmen remarked that when at work his right shoulder-blade projected to an unusual extent, and he himself noticed that on leaning back in a chair, the right shoulder-blade was the first to touch the back, so that the lower angle became sore.

On stripping the patient his general muscular development was found to be good. There was no appreciable difference in size between the muscles on either side, except that the inferior digitations of the serratus magnus were very evident on the left side, and absent on the right. This became more evident on making the patient rapidly extend his arms forwards (as in striking straight from the shoulder), when the digitations on the left side started up into marked prominence, while those on the right did not become visible. This movement was also executed more forcibly with the left than with the right arm. On examining the back (his arms hanging by his side) it was found that the distance from the posterior border of the scapula to the middle line was as nearly as possible equal on the two sides. There was slight flattening in the position of the right rhomboid muscles. The angle of the right scapula was about one inch lower than the left; and, compared with the latter, it made a very marked projection, and its outline was much more evident. He could raise both arms with equal facility to a position at right angles to the trunk and in the same plane. In this position the prominence of the right scapula became more marked, it being possible to introduce the fingers between the lower angle and the ribs from behind. The left arm could be raised straight up above the head, while the right could scarcely be raised beyond the position at right angles to the trunk. On lifting the arm with the hand it could be raised to the same position as the left arm without difficulty and without causing pain, the structures about the joint offering no resistance. The undue prominence of the right scapula was most marked when he stood with both arms extended forwards at right angles to the trunk. In this position the whole bone stood out like a veritable hump on the right side of the back. The reaction of the right serratus magnus and of the right rhomboid muscles to the interrupted current was distinctly diminished, while their reaction to the constant current was increased. There was also qualitative change in the reactions, and the contractions were of the sluggish form seen in the reaction of degeneration. The other muscles on the right side, including the trapezium and the levator anguli scapulae, gave normal reactions, as did all the muscles on the left side. The urine contained about one-eighth albumen.

On April 12th the following note was made:—Under the influence of general treatment and occasional applications of electricity, faradaic and galvanic, the patient has steadily improved. He can now raise the right arm considerably beyond the position at right angles to the trunk. Faradaic excitability of the right rhomboids and serratus magnus has slightly improved (?). Their galvanic excitability is increased, the reaction being sluggish, acc = ccc. On April 26th he was seen again, and the affected muscles showed further signs of improvement.

Remarks by Dr. FERRIER.—Dr. Ferrier considered that this was a case of combined paralysis of the serratus magnus and rhomboid, resulting in all probability, as not unfrequently happens, from over-exertion. Though the patient was in some measure exposed to lead poisoning in his work, yet there was no indication of any of the toxic effects of lead otherwise. That the paralysis did not depend on a limited anterior polio-myelitis was shown in the entire freedom of the deltoid and other muscles which are innervated from the same segment of the spinal cord and its corresponding motor root. The cause of the paralysis was therefore most probably a peripheral affection of the nerve of the serratus magnus and rhomboid, induced by the constant strain and fatigue involved in the patient's occupation. The serratus magnus occasionally suffers alone, and some discussion has taken place as to the exact position which the scapula assumes under such conditions. Perhaps in some of the cases described the conjoint affection of the rhomboid has been overlooked. When the serratus magnus alone is paralyzed, the posterior border of the scapula is drawn nearer the vertebral column, and the inferior angle is somewhat raised and stands off the thoracic wall. This deformity, as has been well explained by Seeligmüller, is due to the unantagonized action of the rhomboid, together with the action of the muscles attached to the coracoid process. In this case, when the arm was hanging quietly by the side, there was no appreciable difference between the distance of the two scapulae from the vertebral column, and the right inferior angle was somewhat lower than the left. This was clearly due to the conjoint paralysis of the rhomboid. Had this not also been paralyzed the deformity described by Berger and others would undoubtedly have occurred. But the deformity was brought out in a most striking and pronounced manner when the arm was extended forward and slightly adducted. The scapula then turned on a horizontal axis passing through the spine, by the agency of the muscles attached to the coracoid process, and the posterior border not being kept applied to the thoracic wall, owing to the paralysis of the serratus magnus, stood off like a wing. The electrical reactions of the affected muscles were such as are characteristic either of peripheral paralysis or of anterior polio-myelitis. The comparatively rapid recovery was such as is seen in the milder forms of peripheral nerve lesion.

MANCHESTER WORKHOUSE HOSPITAL.

NOTES ON A COMPLICATED CASE OF ACUTE RHEUMATISM; ERYTHEMA TUBERCULATUM; ACUTE TONSILLITIS; DYSPHAGIA AND DYSPNOEA; TRACHEOTOMY; BRONCHO-PNEUMONIA; RECOVERY; REMARKS.

For the report of the following notes we are indebted to Mr. C. B. Voisey, M.R.C.S., resident assistant medical officer.

M. H—, aged thirty-one, married, laborer, was admitted on Nov. 14th, suffering from rheumatic fever, which he attributed to exposure to wet and cold a few days previously. For ten days before admission he had been in bed at home, suffering intense pain in the joints, and for one or two days was covered with a red and irritable rash, which he described as similar to the one (erythema tuberculatum) that developed during the time he was in hospital. Temperature on admission 103.4°. No albumen in the urine.

The notes taken on admission were as follows:—He was a man of intemperate habits, and had syphilis twelve years ago; but he appeared strong and

had never suffered from any acute illness except an attack of pleurisy last Whitsuntide, which confined him to bed for three weeks. His father and mother are both dead. The former suffered severely from rheumatism; the latter and a sister died from consumption; of the other eleven children only one brother is living. From Nov. 14th to 25th inclusive, the case was one of ordinary acute rheumatism, progressing favorably under the ordinary treatment by twenty-grain doses of salicylate of soda and bicarbonate of potash every three hours. The pain and swelling disappeared from the affected joints (knees and wrists) on the 18th (when the medicine was ordered to be taken thrice daily), when the temperature was normal. On the 26th, acute inflammation of the left tonsil developed (temperature 103.2°; pulse 120) and the symptoms became so urgent during the succeeding twenty-four hours, owing to the rapid increase in the size of the gland, that repeated scarification was practiced, and the patient placed in a steam-tent. About this time, too, the body was observed to be covered with a deep rose-colored rash, consisting of round or oval elevated patches of skin, varying from an inch to two inches in diameter (erythema tuberculatum), most marked over the chest and arms and least so on the legs. Subjacent and slightly adherent to many of the erythematous patches hard nodules were developed in the subcutaneous tissue, which were quite free from attachment to the deeper structures. Such a patch, as described, was situated upon the outer half of the upper and lower eyelids of the left side, involving the neighboring tissue for about three-quarters of an inch. Another was observed on the outer side of the left arm. The backs of both hands were similarly affected. The dyspnoea and dysphagia were only temporarily relieved after each scarification of the tonsil by the removal of large quantities of thick tenacious mucus from the distended follicles; and on the following day (the 27th) the patient's condition became so critical that Mr. James Hardie, the medical officer, performed tracheotomy to prevent immediate asphyxia. After the operation the patient was again placed in a steam-tent, and obtained speedy relief. The erythematous patches and subcutaneous nodules had now lost much of their prominence, and the patches were fast fading. From the time the tonsil became inflamed it was necessary to administer nutrient enemata of milk, egg, and whisky, in which a dose of the medicine was placed every three hours. On the morning of the 28th the only remaining indications of the erythema were a number of bruise-like cutaneous discolorations; but now erysipelas made its appearance on the bridge of the nose, and, during the two following days, had spread rapidly upwards on to the scalp and down over the face. Tincture of perchloride of iron and sulphate of quinine were now prescribed, and by this time the tonsillitis had sufficiently subsided to allow of both medicine and nutriment being taken by the mouth. On the evening of the 30th tightness and constriction across the front of the chest were complained of. An examination revealed rhonchi all over both lungs with dullness and tubercular breathing at the bases posteriorly. Temperature 104.8°; pulse 120. With the subsidence of the erysipelas the lung symptoms became more marked, the cough being very troublesome, the expectoration free and rusty, and the breathing rapid and difficult. The condition of the patient at this time was very critical, owing in part to the lung complication and in part to the inability to take sufficient nourishment, for the tonsil was still slightly enlarged, and the incisions previously made into its substance had assumed a very unhealthy and sloughy

appearance, and were such as to render the act of deglutition extremely painful, if not indeed absolutely impossible. The heart too showed signs of weakness, as indicated by the pulse and the appearance of œdema on the backs of both hands; none in the feet. A careful stethoscopic examination on several previous occasions failed to detect any murmur, and even now only the slightest blowing can be heard over the apex accompanying the first sound. The heart was enlarged, the apex beat being on a level with the nipple line. The occurrence of dropsy in the hands and not in the feet may possibly be explained by the fact of the tissues in the former having been injured by the erythema, etc., and consequently more unhealthy and predisposed to œdema. An examination of the urine on Nov. 29th led to the discovery of merely a trace of albumen, which could easily be accounted for by the high fever; no casts. By Dec. 7th the pulse was very weak, and an attempt to sit up in bed brought on an attack of syncope. The lung complication was treated locally by hot applications to the chest and by the internal administration of a mixture containing tincture of digitalis, tincture of squills, and carbonate of ammonia every three hours. The patient gradually improved, the first manifestation of improvement being indicated by the pulse becoming stronger and more regular, and the dropsy disappearing from the upper extremities. Henceforward convalescence was uninterrupted, and on Jan. 26th, the patient expressed himself as feeling well and strong, and persisted against advice in taking his discharge and returning to his occupation as a laborer.

Remarks by Mr. VOISEY.—The peculiarity of this case consists in the multiplicity of its complications. In addition to the cutaneous eruptions, miliaria, and sudamina, usually seen in many cases of acute rheumatism, and other acute febrile diseases, this case was still further complicated by two other eruptions, erythema tuberculatum and erysipelas. Most text-books agree that one or other of the various forms of erythema may occur in the course of acute rheumatism, but there is a difference of opinion as to the occurrence of erysipelas in such cases. The case is further peculiar as showing, what has been observed before, that acute tonsillitis may be of rheumatic origin, and it is on these grounds possibly that salicylate of soda and bicarbonate of potash have been recommended, the former internally, the latter locally, as efficacious in cases of uncomplicated quinsy.

MIDDLESEX HOSPITAL.

ACUTE PHOSPHORUS POISONING; NECROPSY.

(Under the care of Dr. W. CAYLEY.)

For the notes of the following case we are indebted to Mr. S. R. Dyer, physician's assistant:

A. F—, a healthy, well-nourished girl, aged eighteen, was admitted into the hospital on Monday, April 15th, at 3 p.m. She stated that she had on the Thursday (April 11th) preceding taken two penny bottles of phosphorus paste with suicidal intent.

The mother of the girl stated that the father had died in a lunatic asylum, and that two of her cousins had committed suicide. The girl had sometimes previously had chorea, since when she had been depressed and strange in her manner.

State on admission: Temperature 101°; pulse 68; weak and compressible, but regular. Patient is well-nourished and of good muscular development, complaining of great pain over the epigastric region, vomiting (the matter first vomited the

patient states was luminous in the dark), and of great prostration. Skin harsh and dry, and slightly jaundiced; conjunctivæ are distinctly jaundiced; there are no extravasations below the skin. Percussion note and heart sounds are everywhere normal. The cardiac dullness normal; sounds each at base and apex are clear, but feebly heard. Hepatic dullness slightly increased, extending downwards just below the costal margin; edge cannot be felt on palpation. Spleen normal. Bowels open normally; no diarrhoea or blood with the motions. Tongue thickly coated with a white fur; dry.

April 17th: Temperature 98.6°; pulse 80, regular, but feeble. Urine contains no albumen, but is bile-stained. Pain over epigastrium continues. Evening temperature 100.2°.—18th: Temperature 99.4°; pulse 56. Conjunctivæ and skin are more jaundiced. Evening temperature 101.6°.—19th: Temperature 99.2°. Bowels open twice; no blood with stools. Pulse 116, very feeble, and easily compressible. Cardiac sounds very feebly heard. Evening temperature 102.2°.—20th: Temperature 101.4°. Heart's action and breathing very rapid. Radial pulse is scarcely perceptible. Diarrhoea with bloody stools has now set in. Is very drowsy. Twitching of several of the muscles set in, and the patient lay in a comatose state for two hours, when she died.

The following are the notes of the post-mortem made by Dr. J. K. Fowler:—Body well-nourished and well-developed. Muscles pale and granular-looking. Rigidity present. Peritoneal cavity normal. Intestines distended. Numerous small hæmorrhages were seen in the intermuscular planes. In removing the parietes of the thorax a few ecchymoses were visible on the anterior surface of the lungs, but on turning forward the lungs, and exposing the posterior surfaces of the visceral pleura, it was seen to be almost covered with fine ecchymoses (subpleural), and in the pericardium and endocardium similar changes were found. The right lung weighed 16½ oz.; the left, 13½ oz. The liver was smooth, swollen, of a bright-yellow color, had undergone extensive fatty degeneration, and weighed 68½ oz. The muscular tissue of the heart was pale and granular. There were no fatty striæ (tabby-cat appearance.) The valves were normal and competent. The heart weighed 10 oz. The spleen weighed 6½ oz., was congested and hard. The kidneys were swollen, the surfaces smooth and pale, the cortex marked with fatty striæ, the pyramids of a pinkish tint. The right kidney weighed 5½ oz., the left, 6 oz. The stomach was dilated; it contained a pint and a half of a clotted grumous looking, brown fluid. The mucous membrane was pale and swollen; there were a few small ecchymoses. The intestines contained a quantity of mucus; they were not otherwise altered. The brain was pale and wet, but not otherwise changed.

FOUR CASES OF CONGENITAL DEFECTS OF THE FEMALE SEXUAL ORGANS.

(Under the care of Mr. HULKE.)

In two of the following cases the existence of atresia of the vagina was unknown to the patients until they reached adult life; and in the first it was not discovered until after marriage. When so complete as to prevent the external escape of the menstrual fluid, whether in the less infrequent form of an imperforate hymen, or in the more rare form of imperforation, partial or complete, of the vagina, atresia commonly attracts notice soon after the age of puberty by the supposed absence of menstruation, and the distress occasioned by the distension of the Fallopian tubes and uterus,

and also of the pervious part, if any exist, of the vagina connected with the latter, by the retained and accumulating menstrual fluid. In the first patient, in whom the occurrence of menstruation and the natural appearance of the external parts of generation had caused the internal defect to remain unsuspected, the defect was essentially the persistence of the opening of the lower confluent ends of the Mullerian ducts into the uro-genital sinus, proper at a certain stage of embryonic life. The operation, urgently demanded by her marriage, was justified by the ascertained presence of a well-developed uterus, and the result was satisfactory, for she returned to her husband, impregnation followed, and she was recently delivered after an easy labour of a viable child. In the second case the atresia of the vagina was complete throughout, and it was associated with an extremely imperfectly developed uterus which appeared to be of the cornuate form, as if the Mullerian tubes had remained distinct nearly if not quite to their lower ends, and then had failed to be brought into continuity with the vulval involution of the external surface of the body during that ingrowth of tissue between the rectum and the uro-genital sinus which finally separates these two passages. Under these circumstances no operation for the atresia was practicable. The patient was a spinster, and it was explained to her that marriage would be improper. The presence in the excised ovary of ruptured follicles, not distinguishable from those occurring in the ovaries of normally menstruating women, is of interest in association with the evidence of the absence of menstruation—absence, not retention, since the combined exploration through the urinary bladder and rectum must have detected such swelling as retention would have occasioned. The absence of swelling or painfulness of the herniated ovaries, incidental to ovulation, such as might have led to their discovery in the groins after puberty, is not unusual, and the excision of such herniated ovaries will only exceptionally be necessary. In the present case, in face of the inability to wear a truss on the right side, the patient did not hesitate between a life of distress and disability and the relief held out by an operation. As has always been observed in congenital ruptures of the ovary, the sac contained also the Fallopian tube. In the peripheral continuity of the serous covering of the ovary lying in the labium with the peritoneal sac enclosing it, may be recognized an imitation of the relations of the testis and process of peritoneum acquired by this organ in its passage from the belly to the scrotum. In the third case the increased swelling, with the painfulness of the solid body in the inguinal cyst concurrently with menstruation, left no reasonable doubt of its being an ovary, but the condition here differed from that in the last case by the obliteration of the original continuity of the sac and the peritoneal cavity, which made the resemblance of the sac to the tunica vaginalis in the male sex more complete. In the fourth case it was the upper part of the vagina which was imperforate, the uterus certainly, and, presumably, the ovaries were undeveloped, and no surgical measures were indicated.

CASE 1. Congenital Atresia of the Vagina; Menstruation through the Urethra; Relief by Operation. (From notes by the dresser, Mr. B. C. Scott.)—On Nov. 15th, 1881, a brunette, aged twenty, was brought by her mother to the out-patient obstetric department of the hospital for advice respecting an unnatural condition, which made sexual intercourse impracticable. She had been married nine weeks, and neither she nor her mother had previously suspected anything wrong. She had, it was asserted, menstruated regularly as other women. When

the labia were separated no vaginal orifice was visible, the surface below the urethral aperture being plane. As a digital examination through the rectum revealed the presence of a well-developed uterus, she was sent into the surgical wards for an operation. The very positive statement that she had regularly menstruated made it probable that this occurred through the urethra, and upon the recurrence of menstruation a few days later, this was verified; the menstrual fluid was seen oozing from the urethral orifice from which, when she strained, it escaped in small gushes. Her urine was, however, quite untinted, which made it evident that the outlet through which the menstrual fluid escaped entered the urethra, and not the urinary bladder. This opening was so minute, perhaps so valvularly disposed, that neither by a careful examination with probes, nor by inspection of the urethra when dilated with a speculum, was it possible to discover it. On Dec. 1st, a staff having been placed in the urethra, and a bougie in the rectum, so that the position of these two tubes could be always ascertained, an incision was made below the urethra, between it and the posterior commissure of the labia majora. When the cut had been deepened to the depth of the second joint of the forefinger the escape of a few drops of mucus showed that the upper end of the vagina had been opened. It was seized, drawn over, the opening enlarged, and its edges were attached with sutures to two flaps of mucous membrane taken from the posterior part of the vulva. A glass tube was placed in the passage thus made. The uterus appeared quite normal, and the upper part of the vagina was capacious. Immediate union was frustrated by an attack of erysipelas, which wandered over her whole body and did not finally disappear until the end of the month. On January 25th she was made an out-patient, and enjoined not to neglect to pass daily a full-sized bougie, which she had been taught to use. She was twice readmitted during the course of the next three months, as, owing to her omission to do this, the line of junction of the upper and lower part of the vagina had contracted, making marital intercourse painful. The contraction was easily overcome by sponge tents. Impregnation followed in the summer, and in February she was delivered of a healthy child, after an easy labour induced at the eighth month, induction of labour at this time being thought preferable to allowing her to go to the full term by Dr. H. Davis, under whose care the patient then was. The only circumstance worthy of notice was the detection of a narrow mesial band in the top of the vagina, just below the uterus, which had till then eluded detection.

CASE 2. Congenital Hernia of both Ovaries, probably Bicornuate Uterus; Atresia of Vagina. (From notes by the dresser, Mr. G. F. McMillan.)—A well-grown maid servant, aged twenty, whilst lifting a bedstead felt, as she thought, something give way in her left groin, where she then first noticed an unnatural lump. A few days later the same occurred in her right groin, attended with such sharp pain as to oblige her to lie down. After this, incapable of working in consequence of the painfulness of the swellings, she went into a village hospital, whence, six weeks later, as they appeared to the surgeon in charge to be of an unusual nature, she was sent to the Middlesex Hospital on Jan. 24th, 1882. Her left labium majus contained a firm knot nearly of the size of a small walnut, but of a more oblong figure. It could be easily pressed from the labium through the external ring into the inguinal canal, but it could not be pushed completely through the internal ring into the belly. In the right labium was a similar knot enclosed in a flaccid elastic swelling. This knot could not

be pushed entirely through the external ring, and above it when she coughed the inguinal canal became distended by another swelling, apparently an entero-bubonocoele. The form and consistence of the knots in the labia, suggested their being the ovaries, and their occurrence on both sides, together with the absence on the left side of any omental or intestinal protrusion, raised a very strong presumption of the condition being congenital. The sudden occurrence of pain, and of the larger swelling on the right side six weeks before, which first made her aware of something being wrong, were attributed to a squeeze of the ovaries during the effort to lift the bed and to the supervention of the entero-bubonocoele. It was expected that a properly adapted truss would enable her to return to her employment, and render any operative measure unnecessary. With the left side there was no difficulty, but no pressure could be borne on the right side; and after several alterations of the pad and spring, the removal of the knot in the right labium was decided on, and carried out on Feb. 18th. Upon opening the sac, which was extremely thin, a few drops of colorless serum flowed out. The sac contained a small piece of omentum, which, being quite normal and not adherent, was returned into the belly. The other contents were an ovary with Fallopian tube to one of the fimbriae of the ostium abdominale, of which was attached a small cyst. The other end of the tube, being traced upwards into the canal was found to become continuous with a cylindroid, fleshy body, which projected from the belly through the internal ring into the inguinal canal. That surface of this fleshy body, which projected from the wall of the sac into its cavity, was smooth and invested by a serous membrane, which circumferentially was continuous with the sac, and was therefore an extension of the peritoneum. The evident relation of the Fallopian tube to this singular body, and the consistence and color of this latter, demonstrated it to be the uterus; whilst its shape and its size (about equal diameter to the finger-tip) made it probable that it was one horn of a bifid uterus. An assistant being directed to ascertain whether the part of the uterus accessible per vaginam was natural in form, and whether it moved when the presumed uterine horn was drawn upon, the discovery was then first made that the vagina was imperforate. The ovary with its Fallopian tube was ligatured close to the uterine horn and cut off. Strict antiseptic measures were observed during the operation and afterwards. A slight suppuration occurred, but at the end of three days the wound had closed and she was regarded as convalescent. The ovary was somewhat small. Upon section in its longer diameter, two ruptured follicles were apparent close to the surface; one larger, filled with the usual yellow substance, indicating a false corpus luteum of old date, the other follicle smaller, plugged with a fresh, deep-red blood-clot. In April she was sent to a convalescent hospital, and when last seen, in June, she was able to wear a truss without inconvenience, and to earn her living. After recovery from the operation, a careful examination of the vulva revealed the complete absence of any trace of the vaginal opening. The distinctness with which a sound passed through the urethra into the urinary bladder could be felt by the finger in the rectum, demonstrated the absence of vagina; whilst a small nodule, which was only just within reach of the finger-tip, was judged to be most probably the imperfectly developed womb. Upon inquiry, it was elicited that the patient had never menstruated. Here external genitalia were perfectly developed, and her breasts were rather large for a woman of her stature.

CASE 3. Inguino-crural Cyst, containing a Solid Nodule, which swelled and became harder concurrently with Menstruation. (From notes by the dresser, Mr. Robertson.)—A housemaid, aged twenty-seven, was admitted into the Queen's ward on Nov. 24th, 1882, with a swelling in the left groin, which she had first noticed a few months previously. It was larger, she remarked, during her periods, and it was then painful and tender, but at other times it did not occasion her much inconvenience. The swelling was parallel with Poupart's ligament, above it, and it reached from the distance of the breadth of three fingers from the anterior superior spina ili inwards to the pubes, where it turned downwards between the thigh and the labium pudendi. It was elastic, and it clearly fluctuated; its size could not be lessened by pressure; and no impulse was given it when she coughed. The inguinal part of the swelling plainly occupied the canal. In two places, one in the thigh and the other nearly over the external abdominal ring, the coverings were so thin as to impart to the underlying swelling a distinctly bluish tint; elsewhere the integument had a natural appearance. As regarded its nature, the swelling was evidently not a rupture, and the absence of oedema and agglutination of the parts about it excluded the notion of its being an abscess. The most probable diagnosis was that of a cyst connected with the round ligament.—27th: A puncture with an aspirator gave escape to an ounce and a half of pale straw-colored serum, having a specific gravity of 1020, and containing a large amount of albumen and of chlorides; the cyst quickly filled again, and on Dec. 8th it was again tapped, and then injected with a mixture of tincture of iodine and water. This provoked slight inflammation, evidenced by pain with tenderness and fresh distension of the cyst, and pain radiating down the thigh and leg. The inflammation quickly subsided, and for some time a decrease of the swelling held out promise of cure. On January 3rd, it having, however, become nearly as large as when first seen, it was again tapped, emptied, and injected with an iodine solution. At this time there was noticed (which had before escaped detection) a flattened nodule of oblong form, three-quarters by half an inch in its diameter, laying in the upper and outer part of the cyst near the internal abdominal ring. On the 19th coincidentally with menstruation this nodule became larger and tender. By the 22nd it acquired its previously indolent condition, and she left the hospital on the following day to resume domestic service.

CASE 4. Imperforate Vagina, with an Undeveloped Uterus.—A very puny, weakly girl, aged nineteen, was brought to the hospital on the 14th of August, 1882. She had never menstruated, and as it had been thought she might be suffering from retention, she was admitted into Queen's ward. Externally her genitalia appeared normal, but the vagina ended blindly for an inch above the hymen. Digital examination through the rectum, a sound being placed on the bladder, demonstrated the absence of the upper part of the vaginal tube. At the full depth of the forefinger a small knot of the size of a hazel-nut was detected in the middle line, to the left of which was a still smaller nodule; the former of these was regarded as probably an undeveloped uterus, the latter as an ovary. Under these circumstances no operative measures were proper.

—At the meeting of the Council of the Royal College of Surgeons recently, Mr. J. Tomes and Mr. T. H. Huxley were elected Honorary Fellows of the College.

ST. THOMAS'S HOSPITAL.

FIVE CONSECUTIVE CASES OF SUCCESSFUL OVARIOTOMY.

(Under the care of Mr. SYDNEY JONES.)

FOR the report of the following cases we are indebted to Mr. W. H. Battle, surgical registrar.

CASE 1. Cystic Tumour.—A. W—, married, aged sixty-five, admitted Nov. 8th, discharged cured Dec. 30th, 1882. The following history was obtained: Her mother died of "dropsy," cause unknown; general history of family good. The patient always enjoyed good health until two years ago, when she had an attack of "spasm" in the left lower abdomen, which was cured by treatment, but she has never felt quite right since that time. Last April she noticed a swelling commencing in the left inguinal region, and this has gradually increased until the present time. She has had severe pains in her abdomen on each side, but the pain has not been accompanied by any vomiting. Catamenia ceased fifteen years ago. Had slight difficulty in passing urine some months ago, but has had no other inconvenience from the swelling beyond that caused by the size of the tumour. The tumour, which consisted apparently of a cyst and more solid portion, extended from the pubes to just above the umbilicus, and bulged more towards the left side, the measurement being one inch more than on the right, whilst the dullness on percussion extended higher to the right than to the left of the umbilicus. It was fairly movable from side to side, and the uterus was normal and free. The viscera appeared healthy, no trace of disease being found. The patient complained of pain in the abdomen over the tumour, increased by exertion, but there was no rise of temperature and she was otherwise in good health.—21st: In the afternoon Mr. Sydney Jones operated, the patient being under ether. An incision five inches long was made below the umbilicus, in the median line. The cyst was easily exposed, but the wall was brittle and some gelatinous fluid escaped during the puncture with trocar, but it did not enter the peritoneal cavity; the cyst having been emptied of its contents, three large omental adhesions were separated, after ligature, and the tumour having been drawn forwards the pedicle, which was rather broad, was tied in two halves by means of stout silk ligatures, which were cut short. There was some ascitic fluid in the abdomen. The abdominal cavity was sponged out carefully, and the wound closed by means of five deep silk and some superficial catgut sutures. The operation was carried out under the spray, and the wound dressed antiseptically. Further examination of the tumour proved it to have consisted of one large principal cyst, containing about three pints and a half of gelatinous fluid, and an apparently more solid portion, weighing 3 lb. 11 oz., consisting of a number of cysts of various sizes aggregated together, with only a small amount of more solid material. The right ovary was healthy. At 8.30 p.m. she was comfortable. Pulse 112, temperature 98° 8'; an hour later pulse 80, temperature 100° 4'.—22nd: The temperature at 2 a.m. 100° 6'. There was a gradual fall to normal, and the highest recorded temperature during the further progress of the case was 99° 8'. On the eighth day the wound was dressed for the first time, it was firmly united, the sutures were removed, and the abdomen supported by broad strips of strapping. Antiseptic precautions were, however, continued until December 12th, when a flannel bandage was applied over the strapping. The use of the catheter was continued until the 26th; the bowels acted after enema on December 29th. The diet was as follows:—Until the 24th she

was only allowed iced milk in small quantities, on that date chicken jelly and Brand's essence of beef; on the 29th, custard and two ounces of wine; December 1st, boiled sole; 2nd, beef-tea added; 7th, minced chicken; 25th, plum pudding. She left cured on December 30th, wearing an abdominal belt.

CASE 2. Multilocular Cyst.—L. E—, aged twenty-six, single, was admitted under the care of Mr. Sydney Jones on November 9th, 1882, and discharged cured on January 10th, 1883. Family history good. Her own health had been good until five years ago, when she was admitted to an asylum, where she remained for two years. Five months ago she had "stoppage of the bowels," lasting for a few days; she then noticed swelling in the right side. The catamenia had been irregular for some time, and she has lately had menorrhagia, with only a few weeks' interval free. There has been a good deal of pain in the abdomen recently. She was tapped in August, and the fluid is said to have been "typically ovarian."

When admitted she was rather emaciated, very nervous, and emotional. The abdomen was greatly distended, the walls being tense and shining; there was dullness all over the front and a distinct thrill from side to side. Girth at umbilicus forty-one inches. The labia were swollen, but there was no œdema of the legs. The patient complained of pain on micturition, but the urine was normal. There were no other pressing symptoms. The uterus was quite free, and there was no projection in Douglas's pouch. The thoracic organs were healthy, though the heart was displaced upwards. After admission she complained of pain in her back and loins, and there was a steady increase in the size of the abdomen, the girth on December 8th being forty-four inches and a half, and the measurement from ensiform cartilage to pubes having increased one inch and a half. The quantity of urine passed in twenty-four hours varied from 12 to 25 oz.

On Dec. 12th Mr. Sydney Jones operated. Ether having been given an incision six inches long was made in the median line below the umbilicus, and the cyst exposed, after a careful dissection through the abdominal wall; this was tapped, but the size of the tumour was not much diminished on account of the large number of comparatively small cysts. The trocar being pushed from the primary puncture into some of these, the size was reduced, and after enlargement of the abdominal wound upwards, two or three strong adhesions, chiefly on the right side, were secured and divided between double ligatures. The tumour was drawn forward, and after its size had been further diminished, it was possible to get at the pedicle, which was connected with the right side, and tied with a double silk ligature. The left ovary was healthy. The peritoneum was well cleansed, and the wound closed with alternate silk and catgut sutures. The quantity of fluid was twenty-nine pints, and the weight of the more solid portion 7 lb. 3½ oz. A suppository of morphia was given after the operation, and later in the day seven minims of solution of morphia were given subcutaneously, patient having become very restless, and complaining of pain.—13th: She had slept about five hours, and had vomited four times during the night; occasional sickness during the day; complained of thirst and restlessness; only allowed ice. Temperature last night, 99°; this morning, 2 a.m., 100° 2'; 8 a.m., 99° 2'.—14th: Allowed milk and soda-water, one teaspoonful every hour; no pain or sickness; restless and low in the morning, but inclined to sleep in the evening.—15th: Allowed two teaspoonfuls of milk and soda-water every hour; is brighter and better; sleeps a good

deal; no further sickness.—17th: Passed urine without catheter; quantity increased in amount.—18th: Taking chicken jelly, and as much milk as she wishes; some pain and tenderness in the right flank.—19th: Wound dressed; sutures removed; taking custard and two eggs.—20th: Bowels acted after enema; allowed sole.—30th: Abdominal belt ordered.

On Dec. 4th the temperature was 100° during the day, but at 4 A.M. on the 15th had fallen to 99·8°, and it did not exceed this point during the remainder of her stay in the hospital. She left cured on Jan. 10th, 1883, twenty-nine days after the operation.

CASE 3. Cystic Tumour.—A. B.—, aged thirty-nine married. Transferred to the care of Mr. Sydney Jones, from Charity Ward, on Oct. 26th, 1882, and left, cured, on Jan. 10th, 1883. Nineteen years ago she had an attack of rheumatic fever. Catamenia regular until two months and a half ago; married seventeen years, no children, no miscarriages. Three years ago she began to suffer from pain in the right side of the abdomen, and soon after noticed a swelling there. This has gradually increased, and she has had occasional pain; when admitted she still complained of this pain in the right side of the abdomen, and said that it extended down to the hip. The abdomen, which was much enlarged, measured at umbilicus forty-two inches, and was almost filled by a large tumour, extending from the pubes to above umbilicus; percussion seemed dull all over this, but resonant in the flanks; it projected more on the right side, there was a thrill over this part of the tumour, but it was unequally conveyed in different directions, and there was a more solid portion felt to the right, and extending from beyond the umbilicus on the left side down into the right flank. The superficial veins were enlarged. There was slight cough and some dyspnoea on exertion, but nothing abnormal detected on physical examination of the chest, excepting that the cardiac dullness could not be defined. Urine: sp. gr. 1030; no albumen, no sugar. There was slight œdema of the left leg.

On Oct. 31st, the patient was placed under ether and Mr. Sydney Jones operated. An incision was made in the median line below the umbilicus for about five inches downwards; the peritoneum was divided after the bleeding points had been secured by catgut ligatures. The surface of the tumour was thus exposed and tapped; nineteen pints and a half of gelatinous fluid having been drawn off, the cyst was drawn forwards, and the pedicle, which was long and slender and connected with the right ovary, was transfixed and tied in two parts by stout silk ligatures. A bleeding point was noticed in the stump of the pedicle, and this was secured by a ligature. There were no adhesions. The left ovary was somewhat irregular on the surface, but otherwise healthy. At 9 P.M. the pulse was 100, the patient comfortable and slightly perspiring; temperature 99·8°.

Nov. 1st: Slept for about four hours during the night; has vomited three times since operation; complained of pain in abdomen, which is now relieved by morphia. Morning temperature 94·8°, evening temperature 100·8°—2nd: Pulse 100; respiration 32. No pain, some thirst; up to the present is only allowed ice. Morning temperature 98·8°; evening temperature 101·2°.—3rd: Allowed milk. Morning temperature 99·6°; evening temperature 100·2°.—5th: Some cough complained of; passing urine without use of catheter since yesterday; and sleeps well without morphia.—7th: Wound dressed antiseptically; no suppuration. Silk sutures removed. Urine acid but containing a little mucus.—8th: Bowels acted after simple

enema. Complaining of frequent micturition. Cough relieved by cascarrilla mixture ordered on the 6th. There is a sanguineous discharge from vagina; this was supposed to be due to return of menstrual period, but on the 10th she aborted.—13th: Allowed fish.—14th: Wound redressed, and antiseptics left off. Supported by strapping.—24th: This morning the wound reopened at the point and gave exit to a small quantity of pus. The temperature, which for two nights had been as high as 102°, became normal afterwards and continued so until Jan. 2nd, when there was a slight rise to 100°, owing to a localized collection near the wound. These collections kept her in bed longer than usual, but she left cure Jan. 10th, 1883.

CASE 4. Multilocular Cyst.—E. J.—, aged forty-four, married, was admitted Jan. 11th and left cured Feb. 2nd, 1883. She had had one child born in 1876, then two miscarriages, and in March, 1882, a second child, which, however, only lived eight hours. There was nothing unusual during the course of the labour, but afterwards the abdomen did not appear to be materially diminished in size; she had noticed that it was unusually enlarged before the confinement. Since March there has been a gradual increase unattended with pain until a fortnight ago, when she had rather severe pain in the left side, which prevented her from sleeping. There has been considerable discomfort from food during the last three weeks.

The following was the condition on admission:—The abdomen is considerably distended, projecting downwards and forwards, the general appearance being that of separation of rectus and attempt at hernia of abdominal contents; there is distinct forcing forwards in median line on coughing. The umbilicus is obliterated; there is dullness on percussion over the whole front of the abdomen and into the left flank, whilst resonance is found above and in the right flank; there is a distinct thrill all over the tumour, which is freely movable in parts beneath. Girth forty-one inches and a half; measurements equal on each side; thoracic viscera healthy; no albumen in urine; uterine axis normal, though somewhat increased in length.

On Jan. 19th ether was given, and Mr. Sydney Jones made an incision about six inches in length between the umbilicus and the pubes, in the median line. The wall of the cyst was intimately adherent to the peritoneum, and was very difficult to separate. The cyst was incised and a large quantity of blackish fluid escaped; two distinct cysts were incised during the operation, the contents of the larger one being entirely fluid; from the smaller one there escaped with the fluid much shreddy broken down fibrinous material. The cyst wall was more easily separated after the emptying of the contents, and it was then drawn forward, the adhesions, which were somewhat numerous and firm, being divided between double ligatures of catgut as they presented themselves to view. The tumour was connected with the right ovary, the left being healthy. The fluid removed measured eighteen pints, the solid weighing 1 lb. 10 oz. A suppository of morphia was given directly after the operation, and she slept for five hours, waking at intervals. Morning temperature, 99·2°.—20th: Since 9.45 last evening has been occasionally sick, bringing up about half a teaspoonful of fluid. At 1 this morning is comfortable, complaining only of slight abdominal pain; relieved by injection of five minims of solution of morphia twice during the day. Morning temperature 99·8°; evening temperature 100·4°; pulse 100.—21st: Some flatulence in the night, during which she slept three hours; no further vomiting; scarcely any pain. Pulse 98; morning

temperature 99-8°; evening temperature 100-2°; pulse 98. Milk in quantities of a teaspoonful at a time.—22nd: Chicken jelly.—26th: Wound dressed antiseptically; a little suppuration along the track of the sutures, but dressing hardly stained by the discharge. Silk sutures removed.—27th: Bowels opened by enema; allowed boiled sole and four ounces of wine.—31st: Redressed antiseptically.

Feb. 3rd: Antiseptics discontinued, and a lotion of chloride of sodium with warm water substituted. The incision wound has healed perfectly, but there is still suppuration in track of sutures.—9th: Opening enlarged with probe-pointed bistoury.—14th: Got up.—22nd: Went to a convalescent home in good health, thirty-four days after operation.

CASE 5. *Multilocular Cyst*.—E. S—, aged fifty-six, single, was admitted on April 29th, and discharged cured on June 1st, 1883. Between four and five years ago she noticed a swelling in the left groin, which went away under treatment, and she was not troubled further until eighteen months ago, when it reappeared, as she thought; this has gradually increased, but more rapidly since Christmas. She has suffered from pain in the head and between the shoulders, but not from pain in the abdomen. Catamenia, scanty but always regular, ceased ten years ago. There were no pressure symptoms. On examination of the abdomen a pyriform swelling was found, extending to four inches above the umbilicus and across to the right; there was dulness over the whole of this, but resonance in the flanks. Marked thrill on palpation. Girth 37 in., and from the umbilicus to the anterior superior spine two inches more on the left side. The thoracic and other organs were apparently healthy. There was no albuminuria. The patient was sallow and very thin.

On May 1st, Mr. Sydney Jones performed ovariectomy. An incision four inches long exposed the cyst, and this was tapped, fourteen pints of fluid being drawn off. The cyst wall was then drawn out through the opening, and separated from the left side by ligature (silk) of the pedicle, which was of fair length, but somewhat soft, and containing some varicose veins. The ligature cut into the structure of the pedicle, allowing considerable hemorrhage, and another embracing the whole was applied below. There were no adhesions. The cyst was found to be multilocular, one of the compartments containing a large clot. The right ovary was healthy. The wound was closed by means of alternate catgut and silk sutures, and the whole operation, which was carried out with strict antiseptic precautions, was concluded within thirty-five minutes.—2nd: She vomited once at 9 p.m. last night, and required an injection of morphia at 6 p.m. to relieve the pain. She has slept fairly well. Temperature 98-4° to 101-4°.—3rd: No sickness; slept well after morphia injection. Temperature 100° to 100-2°.—4th: Pain occasionally not enough to require morphia; ice and one ounce soda water every hour. Some mucus in the urine, which is drawn off by catheter. Temperature 98-8°.—6th: Temperature normal yesterday and to-day in the morning, but going up to 100-8° in the evening. A good deal of flatulence and some pain, for which morphia was given.—7th: Dressed, looking well; hardly any discharge. Temperature in the afternoon 103°. Vomited once. Chicken broth and Brand's essence.—8th: Wound redressed, all silk sutures removed; much abdominal distension. Ordered enema simplex. Temperature 97-8° to 100-2°. Stimulants ordered.—9th: Bowels acted four times after enema, and the patient much more comfortable; has less pain, and there is less distension.—10th, p.m.: Considerable pain over the bladder and inability to pass urine, which is thick, sp. gr. 1022, and contains

mucopus. Temperature normal.—15th: Urine improving in appearance, but the patient still unable to pass it herself. Temperature 100-2° last night, 99° this morning. After this date the temperature was 100-2° at 2 a.m. on the 16th and 17th, but excepting that it continued normal till she left. She was up on the 19th and rapidly regained strength; there was slight suppuration about one of the punctures left by the silk sutures on the 22nd, but otherwise convalescence was not retarded.

WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL.

CEREBRAL EMBOLISM IN A GIRL AGED FIFTEEN YEARS, FOLLOWED BY EXTENSIVE HÆMORRHAGE AND DEATH.

(Under the care of Dr. TOTHERICK.)

For the following notes we are indebted to Dr. E. W. Hope, house-physician:—

Eliza W—, nursemaid, aged fifteen years and a half, was admitted Feb. 21st. The only previous illness was an attack of acute rheumatism eight years before; in later years slight shortness of breath and palpitation on exertion had been noticed. Feb. 20th, whilst sweeping the floor, she suddenly became faint and giddy and fell to the ground. There was no loss of consciousness, but on attempting to rise she found that there was complete loss of power of the left arm and leg. The seizure was accompanied by severe pain in the head.

On admission, the following notes were taken:—She lies quietly in bed; eyes closed; respiration tranquil. She is fairly nourished, pale, somewhat anæmic; complains of headache; articulates distinctly and swallows without difficulty. Temperature 102-6°. There is complete paralysis of the left arm and leg. On showing the teeth, the mouth is drawn to the right side; tongue protruded to the left; muscles of the eyes unaffected. There is a blowing mitral systolic bruit; pulse 108, fair; urine 1016, contains a trace of albumen.

No new symptom occurred until the evening of the 22nd, when the girl complained of nausea and headache, followed by vomiting. Almost immediately afterwards, without any convulsion, she became completely unconscious; respiration slow, irregular, and stertorous, 8 to 12 per minute; pulse 72, fairly regular and full; eyes turned upwards and to the right; pupils somewhat small, irresponsive to light; face pallid, covered with clammy sweat, head turned to the left; urine voided unconsciously. Respiration soon increased to 30 per minute, shallow and regular; pulse 120 per minute. She remained unconscious about two hours; face and lips extremely pallid; eyes closed as if asleep. With the return of consciousness, pain in the head was complained of. There was dorsal decubitus, and occasional alteration of the position of the right limbs; the left hemiplegia was very marked, and the head turned towards the paralyzed side, both eyeballs turning to the right. Up to the 28th there was slight improvement in the condition; headache, however, persisted, and the albuminuria slightly increased. Flushing of the face, followed by slight perspiration, frequently occurred. Control over the sphincters was not re-established. On the evening of the 28th, whilst lying quietly, coma suddenly occurred; respiration was stertorous, and death ensued in a few minutes.

Necropsy revealed the following conditions:—Heart: loosely attached fibrinous vegetations on the anterior cusp of the mitral valve; otherwise healthy; weight, 10 oz. Brain, superficial veins of both hemispheres full and prominent. On opening the ventricles they are found to be occupied

with soft, dark, blood-clot, which extends through the foramen of Munro, also along the iter to the fourth ventricle, of which it forms a complete mould. Blood-clot extends from the fourth ventricle to the subarachnoid space surrounding the medulla, covering the pons, and extending down the spinal cord. In the cerebral substance, immediately external to the right corpus striatum, is a cavity from which blood-clot escaped when the ventricles were opened. The walls of this cavity are discolored and puffy; on cutting into the inner wall, which is formed by the right corpus striatum, numerous small clots are met with; this is clearly the point from which the hæmorrhage arose. In the right middle cerebral artery, at the point of its subdivision into three, a small fibrinous vegetation is impacted, from which clot extends a short distance up that subdivision which pierces the substance of the brain.

SUSSEX COUNTY HOSPITAL.

EPITHELIOMA OF TONGUE; HÆMORRHAGE FROM LINGUAL ARTERY; LIGATURE OF COMMON CAROTID; DEATH FIVE MONTHS LATER; NECROPSY.

(Under the care of Mr. N. P. BLAKER.)

For the notes of the following case we are indebted to Mr. B. Scott, house-surgeon:—

W. H—, aged forty-five, a grocer, was admitted on Dec. 24th, 1881, with an ulcerated tongue, which on the previous day had bled profusely. The tongue was first affected three months before, when a sore appeared on its right border. The patient did not seek treatment till a week before admission. No history of syphilis could be elicited.

State on admission: There is very extensive ulceration of the right side of the tongue from the tip to the epiglottis; the ulceration extends on to the floor of the mouth; the edges of the ulcer are everted and the surrounding parts are hard; there is an enlarged gland beneath the jaw; the breath is foul; he has not any pain to speak of; on the same side the last molar tooth is prominent and black. At 4 P.M. hæmorrhage again occurred. Allowing for the saliva, he must have lost a pint of blood. Tincture of perchloride of iron was applied with lint, and the bleeding gradually stopped. About an hour later bleeding recommenced. It was at once stopped by compressing the carotid artery against the transverse process of one of the lower cervical vertebrae. The patient became very blanched. A third of a grain of morphia was injected subcutaneously. As he fell asleep he had a few convulsive starts in the limbs, and breathed stertorously; he recovered in about a minute. There was profuse perspiration at the time, especially at the head. Chloroform was given, and Mr. Blaker tied the common carotid artery. No difficulty was experienced. A silk ligature was used, and one end was left hanging from the wound, which was stitched with silver. Beef-tea, arrowroot, brandy, and laudanum were given by the bowel every three hours.

Dec. 26th: Patient is comfortable. Twenty hours after the operation the temporal artery was felt pulsating indistinctly. Takes fluid by the mouth. Temperature 98°, pulse 120.

Jan. 2nd, 1882: The tongue has much improved in appearance. The edges of the ulcer are less everted, and the ulcer itself looks as though it were healing.—12th: Complains of faceache up to the right ear.—20th: Has had a mild attack of erysipelas. Condition is now very satisfactory. The ulcer on the tongue looks much more innocent. The edges are bevelled and covered with epithelium.—23rd: The ligature came away with

slight pulling (twenty-ninth day after operation).—29th: Feels and looks ill. Tongue dry and coated. Diarrhoea. Pain in the left arm from the shoulder to the elbow. No affection of the left leg.—31st: Has pain in the right knee. This is hot, very tender, and is tense with fluid. No shivering. Cheeks flushed. Morning temperature 97.4°, evening temperature 101°.

March 1st: The arm and knee are much better again. Morphia injections have been given for pain in the tongue and right side of the face and head.

April 1st: His condition is much worse. The ulceration on the floor of the mouth has extended, and induration passes from beneath the jaw to the wound of the operation, which has reopened.

May 12th: He is very weak and emaciated; brought up about half a pint of blood, which probably came from the tongue. This is the first time hæmorrhage has occurred since the operation.—27th: To-day he died from exhaustion.

Necropsy.—Very thin. There is a large sloughing wound in the right side of the neck. The two ends of the occluded carotid artery are seen lying in this wound. The sterno-mastoid muscle of this side is converted into a hard cancerous mass. The glands are infiltrated. (Brain could not be examined.) Two-thirds of the tongue are ulcerated away, and the rest is infiltrated. The cancer extends down into the right side of the neck, but does not attack the larynx or pharynx. Epiglottis cedematous. No cancer elsewhere.

BOROUGH HOSPITAL, BIRKENHEAD.

CASE OF PERSISTENT HICCOUGH; NECROPSY; REMARKS.

(Under the care of Dr. STEVENSON.)

For the following notes we are indebted to Mr. M. J. Bernstein, M.B. Ed., house-surgeon:—

Timothy F. B—, aged forty-four, a stonemason, was admitted on May 19th, 1881, suffering from hiccough and pain in the lower part of the back and loins. The family history was good generally; but both parents died at the age of fifty-seven, the father being said to have died of "debility and wasting."

About fifteen years before admission the patient had some acute urinary complaint; two years before had erysipelas of face after being exposed to the cold and wet. During the intervals and until three weeks before admission, he had enjoyed good health, except that he had been losing weight.

About April 28th he was seized with a pain in the lumbar region of the spine. The pain gradually spread round to the loins and epigastrium, so that he had to give up work on May 11th. On the 14th he began to be troubled with hiccough; the urine became scanty and thick.

After admission the patient lay in bed on his right side and hiccoughed with scarcely an intermission. His complexion was pale; skin moist; temperature normal. The thorax, on examination, presented no abnormality. The pulse was 80, firm and regular; tongue white and moist; abdomen distended and tympanitic; liver dullness normal. There was considerable tenderness over all the abdomen, but more particularly over the iliac regions. The bowels had been confined since the 14th. Bismuth and hydrocyanic acid and soda-water and ice were given internally. Turpentine stupes were applied over the abdomen, and an enema with an ounce of castor oil was administered.

May 20th: Hiccough much diminished, and abdominal distension still considerable.—21st: A drop of croton oil with castor oil in the evening.

Slight fits of hiccough only at intervals. Abdominal tenderness is nearly gone.—27th: Has had occasional attacks of hiccough. Still some tenderness in abdomen, and pain in the back.

June 7th: He has been pretty free from the hiccough, but the pain in the back is worse, and there is still some abdominal tenderness. The patient was, at his own request, discharged on the 9th. Before leaving he was anesthetized, and his abdomen was thoroughly explored, but without anything abnormal being observed.

The patient was readmitted on September 12th. He had been in the interval an in-patient at another hospital, and now brought with him a medical certificate stating that he had aneurism of the abdominal aorta. He was much emaciated, his countenance had a very anxious expression, and he had considerable abdominal tenderness and pain in the back. On pressing on the epigastrium midway between the xiphoid cartilage and umbilicus over the region of the aorta, a pulsation was distinctly felt. During the following week he became much weaker; the arms and hands were in a state of tremor, and the breath was observed to be fetid. On the 21st he was attacked during the night with hiccough, and his voice was partly gone. Hiccough was more or less continuous, even during sleep, till the 26th, when there was some amount of tympanites. Trembling of the hands was very violent, but could be controlled. On the 25th he was slightly delirious. The hiccough was continuous till the 28th. The temperature was normal, pulse regular. On the 29th, after the administration of a purgative and fifteen drops of rectified spirits of turpentine, the hiccough was relieved, though on the following day it was as bad as ever, and the patient was delirious through the night. He died next morning, on the 31st.

Necropsy.—The body was extremely emaciated. *Thorax:* The pericardium was completely adherent to the heart, and could only be torn off with difficulty. The heart was extremely small; the muscular substance being soft and friable, but the orifices normal. The upper lobes of the lungs were firmly attached to the chest walls by old pleuritic adhesions. At the apex of the right lung there was the appearance of a small pus cavity which had been opened in tearing the lung out. The substance of the lung was fairly crepitant, but was studded all over with hard caseous nodules about the size of peas, some much larger. At the root of each lung, surrounding the bronchus, were large caseous masses, three on the right and two on the left side, about the size of almond nuts. In the abdomen nothing abnormal was observed, excepting that there was little or no fat in the walls or in the omentum. The aorta was quite normal in calibre and substance.

Remarks.—The first remarkable point in this case is the almost complete absence of physical signs, and of symptoms that would tend to reveal the true nature of the case. The absence of the former is sufficiently explained by the condition of the lungs as they were seen at the dissection. While there was quite enough healthy lung tissue to carry on the respiratory function, the small caseous nodules scattered all over would scarcely be recognized by any physical examination. Indeed, we can scarcely consider the condition of the lungs to have been the immediate cause of death. The emaciation came on only at a late stage of the disease, so that we may justly consider the hiccough, which was so prominent and persistent a symptom in the case as it came under observation, was intimately connected with the fatal termination; must, indeed, by its exhaustive effects on the patient have been the immediate cause of

death; and we also consider that the unusual presence of the large caseous masses at the root of each lung, by implicating either the phrenic nerve in front or the vagus behind, may have in some way produced this most unusual symptom of hiccough. It is also noteworthy that the only remedy (and many were tried) that had any effect at all on the hiccough was a strong purgative.

GAOL HOSPITAL, KAIRA.

DEATH FROM AIR IN THE VEINS AFTER PARTURITION.

(Under care of Surgeon D. CHAS. DAVIDSON, Indian Medical Service.)

In March last a Hindoo woman was admitted into the Kaira Gaol Hospital and safely delivered of a female child. The labour was perfectly natural. The head presented, the placenta came away at the usual time, and there was no post-partum hæmorrhage. About three-quarters of an hour afterwards the woman died, without any ostensible cause. There had been no hæmorrhage or convulsions. The patient had been taking some nourishment when she suddenly fell back and expired.

At the post-mortem examination, two hours after death, the uterus was found empty, with large and somewhat distended veins; the right side of the heart contained a quantity of air mixed and churned up with blood, and which escaped in bubbles; the lungs were congested; all the other organs were normal.

This is another case which might be added to the list of those already recorded of sudden death following parturition, presumably due to the entrance of air into the veins; and having occurred in a native of this country, in whom the dangers of childbirth are generally supposed to be comparatively trivial, it may perhaps not prove uninteresting to some of your readers.

LANCASTER INFIRMARY.

CASE OF HYDATED TUMOURS IN THE DORSO-LUMBAR REGION.

(Under the care of Mr. W. HALL, Jun.)

For the following notes we are indebted to Dr. Gilbert, house-surgeon:—

James H—, aged twenty-nine, plasterer, was admitted March 9th, 1883, suffering from a tumour in the back, extending vertically from between the tenth and eleventh dorsal vertebrae to the third lumbar, and horizontally from about two inches and a half on the right of the spines to one inch on the left. It was distinctly lobulated, and had all the characteristics of a fatty tumour.

Six years ago he first noticed a swelling about the size of a small marble, painless and freely movable; it grew slowly, and at the end of three years was the size of a walnut. The next year it doubled in size, and from this time the growth was more rapid, and he had pain on being exposed to wet or cold, which he describes as being like toothache. During the six months before admission the growth was very rapid, and he felt that it was undermining his health, and caused him great pain when stooping, which he has frequently to do whilst following his employment.

On the day after his admission Mr. Hall made a vertical incision about five inches long, and a little to the right of the spines of the vertebrae. The tumour was found to be firmly adherent to the subjacent fascia, and would not shell out, as a lipoma usually does. Whilst being separated from its adhesions its under surface was accidentally wounded with the knife, and then followed a

gush of fluid loaded with cysts of all sizes, from that of a millet-seed to a walnut. Microscopical and chemical examination proved their hydatid character. The tumour having been removed, it was found that a narrow tubular offshoot passed down amongst the deep muscles of the back, and communicated with a cavity about three inches by four in extent, which, on pressure, proved to be full of the same kind of cysts.

After this cavity had been emptied as far as possible by pressure, it was thoroughly syringed with a solution of carbolic acid, and then filled with lint steeped in solution of chloride of zinc. Next day the lint was removed, and a large drainage-tube inserted; the wound was dressed antiseptically throughout; the discharge daily decreased; the cavity gradually closed; and without having had an uncomfortable symptom, the man was discharged cured on April 3rd.

STANLEY HOSPITAL, LIVERPOOL.

COMPOUND FRACTURE OF THE TEMPORAL BONE WITH
HERNIA CEREBRI; RECOVERY.

(Under care of Mr. SHELDON.)

For the following notes we are indebted to Mr. F. W. Pilkington, house-surgeon.

P. D—, aged twelve, was brought to the Stanley Hospital on April 6th last, having received a kick from a horse in the left temporal region.

On admission two small punctured wounds were found, leading down to a fracture of the temporal bone, from which a portion of brain substance, the size of a small nut, protruded. The boy was completely collapsed, and the pulse scarcely perceptible. Antiseptic dressings were used, the patient was kept in bed in a darkened room, ice bags were applied to the head and two grains of calomel were given twice a day with milk diet. For the first four days his condition remained unchanged. On the fifth day the temperature rose to 108°, and he became delirious. This lasted until the tenth day after admission. From that time the temperature gradually fell to normal, the head symptoms rapidly disappeared, and the boy was discharged on May 1st perfectly well. There was very free discharge of pus from the wound after the elevation of the temperature, the protruded brain substance gradually sloughing. This continued until a few days before the boy left the hospital.

Remarks.—Two interesting features in the case are that complete loss of speech occurred after the some of temperature was reached, gradually returning during convalescence; and, secondly, at no time were the sphincters or extremities affected.

Medical Societies.

PATHOLOGICAL SOCIETY OF LONDON.

Sarcoma of Lower Jaw.—*Sarcoma of Bladder.*—*Bacilli of Leprosy.*—*Papilloma of Bladder.*—*Hydatid Cyst in Lung.*—*Ulceration of Intestine.*—*Disseminated Cancer.*—*Gastric Ulcer.*—*Polypus of Stomach.*—*Ulceration of Larynx.*—*Acute Atrophy of Liver.*—*Vacuolation of Brain.*

THE concluding ordinary meeting of the Pathological Society of London was held on May 15th, Dr. Buzzard, one of the vice-presidents, in the chair. By several members consenting to show their specimens as card specimens the session was

closed without any arrears of work being left over.

Dr. Goodhart read the report of the Morbid Growths Committee on Mr. George Lawson's specimen of Recurrent Cartilaginous Tumour of the Lower Jaw, to the effect that the tumour was a spindle-celled sarcoma.—Dr. Goodhart also read a report on Mr. Roger Williams's specimen of Tumour in a Diverticulum of the Bladder, agreeing with Mr. Williams in stating that the tumour was a sarcoma.

Dr. Thin, for Dr. Hillis, of Demerara, showed specimens and a drawing of the Bacilli of Leprosy. Dr. Hillis had sent from Demerara tubercles excised from patients suffering from tubercular leprosy, and sections had been prepared and stained, at Dr. Hillis's request, especially for the Pathological Society. The drawing shown had been made from the preparations, in accordance with Dr. Hillis's wishes, and gave an accurate representation of the bacilli.

Mr. Morgan showed a specimen of Multiple Growths in the Bladder of a Man aged sixty-five. He had had symptoms of irritation of the bladder and hæmaturia for fifteen years. While in the hospital his urine always contained blood. An exploratory incision into the bladder was made in the perineum, and a tumour was felt, together with a velvety condition of the mucous membrane at the trigone; the tumour was removed by the lithotrite, and his symptoms were relieved for six or seven weeks. Then the symptoms returned, and the man died. There was some enlargement of the prostate, and about the trigone were several small tumours, all more or less pedunculated and formed of groups of villi; they were soft to the touch. The bladder was not much hypertrophied, and the ureters only a little dilated. Mr. Morgan thought that the tumours had developed since the operation. Mr. Boyd had examined microscopic specimens, and, although the tumour was too much macerated to prepare perfect specimens, he was able to determine that the growths were papillomata.

Dr. Curnow showed a specimen of Hydatid Cyst in the Lung, obtained from a seaman, aged thirty, who was admitted to the Seamen's Hospital for cough, hæmoptysis, and loss of flesh. In January he suddenly expectorated a great quantity of watery fluid, followed by blood. In March he spat up some membrane, recognized to be hydatid cyst-wall, and it was then discovered that he had once been a shepherd in Australia. He died from exhaustion. The upper left pleura was obliterated, and in the upper lobe of the lung was a very large cavity, occupied by a loose hydatid cyst. The base of the pleura was full of pus; the tissue of the lung was compressed and airless. Echinococci hooklets were found in the cyst. In England such cases were very rare. In Australia they have been numerous. The case was at first taken for apex phthisis and basal empyema.—Dr. Buzzard said that Dr. Bird gave the average amount of fluid drawn from such cysts as eight to sixteen ounces, and he doubted whether such a small cyst could have been successfully tapped.—Dr. Wilks asked if Dr. Curnow associated the hydatid with the shepherd's dog.—Dr. Curnow replied in the affirmative.

Dr. Curnow exhibited a specimen of Ulcerated Intestine, from a man, aged twenty-six, recently returned from Alexandria. The ship took water at Alexandria, and there were other cases of fever on board. He was admitted with enteric fever, but the stools were noticed to be very offensive. On the eighteenth day of the disease the temperature became normal; he convalesced for four or five days and sat up in bed. On the twenty-fourth day

the temperature rose, and pains in the thigh and calf came on. He died on the thirty-first day. No hæmorrhage from bowels; not more than three stools in any one day. The upper part of the jejunum was thin and very transparent in places, swollen elsewhere; about its centre there was one oval ulcer, and many ulcers in the lower part and especially near the cæcal valve, where the whole surface was involved in the ulcers and surrounding swelling. Similar ulcers extended through the colon and into the rectum; some were deeply excavated, others had sloughs adherent to them; the lymphatic glands were enlarged; the spleen was very large. Thrombosis of external iliac vein. The author remarked on the great number of the ulcers, and the extent to which the large intestine was affected; the fact that the ulcers in the large intestine appeared to be older than those higher up; the absence of severe diarrhoea and the man's convalescence for four or five days, although the ulceration was going on the whole time.—Dr. Howard Bendall asked if the man had bathed in the lake, which was worse than ordinary sewage to bathe in.—Dr. Curnow could not say about the bathing; the drinking water on board ship was said to be very bad.

Dr. Percy Kidd showed a case of Disseminated Cancer. In this case new growths were found in nearly all the abdominal organs, in the bronchial and mediastinal glands, in the lung, cerebellum, and in the subcutaneous tissue of different parts of the body. There was an old hæmorrhagic cyst in the left frontal lobe of the brain. The left arytenoid cartilage was necrosed, but no other disease was discovered in the larynx. It seemed probable that the malignant disease originated in the abdominal glands. The growths in the liver were multiple and evidently secondary. The root of the right lung was infiltrated by a very hard growth starting from the mediastinum. The bronchus going to the right upper lobe was much obstructed, and in the corresponding lobe there was some fibroid induration, and a few small, smooth-walled, pus-containing cavities, apparently the result of bronchial dilatation. On microscopical examination the growth proved to be carcinomatous, the harder portions presenting the characters of scirrhus. Sections of the right lung near the root showed a carcinomatous infiltration following the lines of the bloodvessels and bronchi, with much fibroid growth and comparatively slight implication of the lung-tissue itself. In a few sections from the head of the pancreas, which was cancerous, a curious concentric structure was observed. This stricture, which was about as large as a millet seed on section, consisted of a series of regularly disposed concentric fibrous rings, in which were numerous thin spindle-shaped nuclei, also concentrically arranged. At the centre was a minute opening, the walls of which seemed to be lined by an endothelial membrane. These appearances suggested a vascular origin.

Dr. Norman Moore showed two Cases of Gastric Ulcer associated with general Degeneration of Arteries. 1. An ulcer of oval form, about one inch in diameter, two inches from the pylorus on the lesser curvature, from a man aged fifty-six years. All the arteries of the body were highly atheromatous. The posterior third of the left cerebral hemisphere was softened, and the cerebral arteries largely calcified. The gastric artery was almost completely calcified. In the base of the ulcer was a small adherent clot leading into a branch of the pancreaticoduodenal artery, a copious hæmorrhage from which was the cause of death. 2. A commencing ulcer in the middle of the greater curve of the stomach of a woman aged thirty-four years, who died in St. Bartholomew's

of interstitial nephritis, associated with atheromatous arteries, and abundant gouty deposits in joints and other parts. The middle part of the ulcer was covered by epithelium, and consisted partly of blood and partly of necrosed mucous membrane. The ulcer was bounded by a distinct edge. Ulcer of the stomach in patients with healthy arteries had been attributed to embolus. It seemed probable from these cases that in persons with degenerate arteries gastric ulcer might be due to thrombus forming in a calcified vessel.—Dr. Moore also exhibited a Polypus of the Stomach, a soft spherical growth from the mucous membrane projecting at the end of the first third of the great curvature. The patient was a man, aged sixty-eight, who died of bronchitis. It had given rise to no symptoms during life. There were three specimens of the kind in the museum of St. Bartholomew's; but the infrequency of the growth was shown by the fact, that the present specimen was only the second which has been observed out of the last 3,000 post-mortem examinations.

Dr. Norman Moore read a paper entitled Inflammation and Ulceration of the Larynx from a case of Measles and from a case of Scarlet Fever. In the case of measles the child was a boy, aged five years, who died of abscess of the brain following necrosis of the temporal bone six weeks after he was first taken ill. The larynx showed ulceration of cords and of the base of the epiglottis. There was no false membrane. In the case of scarlet fever the ulceration was somewhat more extensive. A considerable tract of epithelium was destroyed; but when fresh no false membrane could be detected. There was a deep ulceration of the fauces without false membrane. The patient was a boy, aged five years, and was the third case of well-marked scarlet fever occurring in a house in the course of three months. These cases were of interest in relation to the remark of Barthez and Rilliet, that laryngitis is more frequent in measles than in scarlet fever.

Dr. Cavafy showed a specimen of Acute Atrophy of the Liver from a man aged twenty. When admitted to hospital he was unconscious, jaundiced, and his urine contained abundance of leucine and tyrosine. Three days before, he had come up from the country, but complained of being unwell; two days later he vomited, and was quite suddenly taken very seriously ill, he then became jaundiced and unconscious. He died the day after admission. There were numerous hæmorrhages, especially in the pleura, peritoneum, and pericardium. Liver weighed thirty-six ounces; the atrophy affected mainly the left lobe, the tissue was not soft, almost tough, surface smooth; on section it presented a brown-red color, being here and there purple. Kidneys showed early fatty degeneration. Dr. Klein examined the liver and other organs. The liver and kidneys showed no bacteria; heart granular and fatty degeneration, no bacteria; the lung showed patches of hæmorrhage with very slight pneumonia, numerous bacteria were seen, long bacilli, short bacilli, and micrococci isolated or arranged in pairs to form dumb-bells. They were most numerous in the inflamed alveoli, and in the walls of vessels. Dr. Cavafy thought these bacilli were of no consequence whatever. The autopsy was made thirty-four hours after death, and the bacilli were probably associated with decomposition, appearing earliest in the organ full of atmospheric air. Waldeyer and Klebs had found bacilli in acute yellow atrophy of the liver.

Dr. Hale White read a paper, written conjointly by Dr. Savage and himself, on Vacuolation of the Cerebral Substance. It was shown that there were nine causes for holes in the brain—viz., 1. Small

processes of the sclerosed meninges of general paralysis dipping into and excavating minute portions of cerebral tissue. 2. In the same disease the sclerosed neuroglia, by its contraction, might give rise to small cavities. 3. Multiple hydatids in the brain. These three conditions were very rare, the authors having no knowledge of the second, whilst the third was almost confined to animals suffering from staggers. Several references to Continental authors were given, and the relation of the "muslin" appearance to the second of the above was pointed out. 4. Another cause was the dilatation of cerebral vessels giving rise to the "état criblé." It was particularly emphasized that this was, in the majority of cases, of no pathological significance. 5. Shrinking of the cerebral convolutions in some cases gives rise to holes in the subjacent cerebral substance. A very good example of this condition was exhibited. 6. Miliary aneurisms would, as Charcot had pointed out, give rise to holes in the brain substance. Some very marked specimens illustrating this fact were shown. 7. The condition known in Germany as the porencephalie, in which a large gap existed in the brain substance. This might communicate either with the exterior or interior of the brain, or both. 8. The Gruyère cheese condition. This, it was pointed out, was quite different from the "état criblé," for it was due to a dilatation of the perivascular lymphatic spaces. Of the causes of this dilatation they were completely ignorant. Probably they must be local, as the dilatation was vascular. The authors showed a perfect example of this condition, in which the whole of the brain, except the lower part of the medulla, was riddled with cavities exactly like those found in cheese, and microscopic specimens exhibited showed clearly that these holes were produced by perivascular dilatation; the shape and direction of the cavities corresponded with those of the vessels. Very few examples of this condition had been carefully described, and only one in England by Mr. Lockhart Clarke, and he referred it to the same cause. 9. The authors showed specimens from two remarkable cases, in which the kidneys, lungs, liver, heart, and brain all contained holes. In the kidney these cysts were due to the dilatation of either the tubules or Malpighian capsules; in the liver they were due to the vacuolation of the hepatic cells; in the lungs and brain it was impossible to come to any definite conclusion as to their origin, but in both these viscera the cavities contained a peculiar material, staining deeply with logwood. Both these subjects were lunatics. Cases in which there were only a few holes, such as patches of softening, hæmorrhage, etc., were not considered to come within the scope of the paper.—Dr. Savage said that of the last two specimens he could say with certainty that the changes were not post mortem. The holes were evident to the naked eye at the autopsy, and the liver looked worm-eaten. The two patients were general paralytics, one a rapid case, the other a chronic one. The word porencephalie had been used for brains with a communication from the outside to the lateral ventricles, and was a pity to have used it for another condition.—Dr. Buzzard said that Dr. Lockhart Clarke's case was one of general paralysis also; the cavities there were filled with blood-vessels and detritus.—Dr. Mahomed remarked that it was a common practice to preserve brains in spirits, but very rare to find a condition of marked vacuolation, which was therefore probably not dependent solely on the action of spirit.—Dr. Hadden recently made an autopsy on a man who died from cerebral hæmorrhage, and the centrum ovale was studded with minute cysts not due to hæmorrhage.

Mr. Swinford Edwards showed a specimen of Comminuted Fracture of the Right Tibia, with nipping of the anterior tibial vessels and nerve; gangrene of the foot came on, and amputation of the leg was performed. Death occurred suddenly. The autopsy showed fatty degeneration of vessels, disease of aortic valves, and calcification of aorta. A large extravasation of blood was found at the back of the leg, pressing upon the posterior tibial artery.

Mr. Victor Horsley showed a specimen of Hypertrophy of one Condyle of the Lower Jaw, removed by Mr. Heath from a patient shown at a previous meeting. The operation had corrected the deformity. A specimen of Enlargement of the Condyle from Half of the Lower Jaw was also shown by Dr. Goodhart for Mr. Eve.

The following card specimens were shown:—Encephalocoele, Uterine Disease in Animals, Remarkable Case of Parasites, by Mr. Sutton; Sarcoma of Bones of Leg, Miliary Cystic Degeneration of Mucous Membrane of Bladder, Sarcoma of Choroid, by Mr. Roger Williams; Complete Obliteration of the Coronary Artery, Cases of Aneurism of the Heart, by Dr. S. West; Necrosed Bone from External Auditory Meatus, by Mr. Roeckel; Hernia Cerebri, by Mr. Bruce Clark.

Mr. F. Churchill showed as a living specimen a girl with Multiple Exostoses.

CLINICAL SOCIETY OF LONDON.

Death from Disease of Ear.—Morphœa.

THE ordinary meeting of the above Society was held on May 11th, Dr. Andrew Clark, President, in the chair. It was decided to hold an additional meeting in June to read and discuss papers already in the hands of the secretaries.

Mr. Dalby read notes of eight cases in which Suppuration within the Tympanum had ended fatally. They were selected to show how, by the consideration of a large number of cases, they might be divided into two very distinct classes. In the first class were those in which a person apparently in good health, with both tympanic membranes entire, is attacked by acute inflammation of the tympanic cavity, ending in rupture of the membrane and a discharge from the ear. Within a period to be counted by days he or she has rigors, and in due course the usual symptoms and endings of meningitis, cerebral abscess, or pyæmia. In the second class, before any serious complications arise, perforations have existed for many years, attended either continuously or at different times by a purulent discharge; and these might again be subdivided into those in which the bone forming the tympanic cavity is diseased and those in which it is not. The questions which were discussed in this paper were as follows:—1. Can it be predicted of any case in an early stage of its history that the probabilities are in favor of a fatal termination? 2. What are the local conditions of the ear, or the symptoms which would point to such a conclusion? 3. Should any special precautions be taken? 4. Is there any treatment of a local kind that should be employed as a protecting influence? 5. Is there any treatment which is often employed in perforations that should be especially avoided? From a consideration of these cases, as well as of many others which had come under the notice of the writer, he maintained that certain conclusions might fairly be drawn from them; at any rate, that although the subject of any perforation of the membrane was in some degree of peril, those in which the bone was diseased were in greater danger than those in which

it was not. It was not difficult to determine whether the bone was affected; a careful examination with the probe under reflected light, exuberant granulations and bony fetor, would decide the question. At the same time it should be remembered that a considerable area of diseased bone in the tympanic cavity is quite compatible with long life, and this is especially the case if the patient has learned to manage the ear by scrupulous cleanliness, and by some sort of protective pad which would keep the external air from the lining membrane of the tympanum. Influences which may lead to a fatal ending are the entrance of sea water into the ear, and the use of strong mineral astringents. Thus in estimating the probabilities of a long life for persons with perforations, their habitual discretion forms a distinct element as to their chances, and this might well be kept in view by insurance companies. Other points for consideration are the urgent necessity of removing a polypus if it prevent the egress of discharge from the tympanum; the important bearing of head pains, whether occurring either at the commencement of the inflammation of the middle ear, or at a later period; the importance of, in recent cases, great profusion of discharge, attended with feelings of giddiness.—Mr. Haward thought it well to be reminded that any patient with a discharge from the ear is in danger of a severe and even fatal illness. It was very important to know whether the surgeon can do anything to prevent these grave complications, for it seems too late to act when grave symptoms have come on. If there be a profuse discharge and dead bone, any obstruction to its outlet should be removed, and astringents appeared to be dangerous. Would it be well to perforate the mastoid bone and make another opening into the tympanum, and so syringe out the suppurating tympanum, a treatment like that employed for similar abscesses in other situations?—Mr. Jessett asked if Mr. Dalby had made the post-mortem examinations in all the cases he had recorded. He had recently attended a girl, aged fourteen, with discharge from the ear for several years; temperature 108°; brawny swelling over mastoid process. The child died next day. Post mortem the bone was found necrosed through into the cavernous sinus, and this had set up pyæmia.—Dr. De Havilland Hall asked if it would not be better to exclude all people with discharge from the ear from life assurance; he had made up his mind not to pass such lives at his office.—Dr. R. J. Lee, some three to four years ago, saw a child about fourteen who was treated for typhoid fever. He found great tenderness of the left mastoid bone, and he had had a discharge from the ear for some months; the mastoid process was opened, but the boy died. A month ago he saw a similar case, a boy with perforation of both tympanic membranes. The discharge had ceased on the left side for a few days. The left mastoid bone was punctured next day; two days later pus flowed from the wound, and from that date the patient steadily improved. The question was, What is to be done in such cases? Were they justified in puncturing the mastoid bone at once? Under what circumstances did abscess form in the mastoid bone? In the post-mortem room they did not often find it.—Dr. Mahomed took exception to the alarmist view of the very great danger of all persons with a discharge from the ear. Very many people so affected went on perfectly well for many years. A few months ago he had a case in Guy's Hospital with convulsions. The boy was very ill, with very high temperature and apparently meningitis. There was slight oedema over one mastoid process, and this mastoid process was trephined. Gas and pus escaped freely. The boy

did not have any further cerebral symptoms, but his temperature did not fall, and he afterwards died of pyæmia. He believed there was no meningitis in that case, but the pus had been evacuated from below the dura mater; the lateral sinus and jugular vein were plugged. He had had two similar, but less severe cases, in adults after measles. The mastoid cells were opened, pus escaped, both patients recovered. He referred to a case of a man who came to the hospital with aural vertigo; he had no perforation or sign of ear disease. Hydrobromic acid was prescribed. Three days later acute meningitis came on and he died; but there was no sign of any disease in the ear, bone, or sinuses.—Dr. Rogers asked if the old treatment of leeching with blisters below the mastoid bone had been used by Mr. Dalby and found successful. He had seen a very large number of cases of ear disease in children, but very few deaths among them. He had known many such cases rejected for life assurance and the Civil Service, and yet be alive and well for twenty years afterwards. He had seen one or two fatal cases of such disease.

Dr. Andrew Clark remarked that it would be well if Mr. Dalby would give a notion of the number of the cases of ear discharge that did well. It would be well, too, to be told what advice Mr. Dalby would recommend to prevent the onset of these fatal complications in this very common affection.—Mr. Dalby did not wish to give the impression of the extreme danger of ear discharge with perforate membranes. The fatal cases he had related were very unusual, but none the less important. He had brought forward eight fatal cases from private practice in ten years, he had seen other four cases during the same time, but in these there were no post-mortem examinations, nor were they typical cases. He thought the proportion of fatal cases was about 1 to 3,000. As regards life assurance he thought it would be quite ridiculous to reject all cases of ear discharge, but he would reject all cases with bone disease. Post-mortems were made in all the eight cases except one, when he, and a physician in attendance, were quite sure that the patient was dying from cerebral abscess. When the discharge was very profuse, head pains acute, and there was tenderness upon deep pressure over the mastoid process, he would advise an opening to be made into the mastoid cells. He thought there was no advantage to be obtained from leeches or counter-irritation in these cases when head symptoms had already appeared.

Mr. C. Higgins and Mr. G. Nettleship contributed a paper on a case of Morphœa in the Region of the Fifth Nerve, with Paralysis of the Intra-ocular Branches of the Third. The subject of this case was a married woman, aged thirty-five, who applied to Mr. Nettleship in November, 1880, with mydriasis and partial cycloplegia of the left eye, with evidence of some dilatation of the retinal vessels and thickening of the coats of the retinal veins, and dilatation both of those vessels and the arteries. She also had single patches of ivory-white morphœa on the corresponding temple, side of the nose, and the upper lip; and a similar but less characteristic change in the skin of the forehead and front of the scalp on the same side, with thinning of the hair. The eye symptoms were of three months' duration. She had not discovered the skin changes. She was out of health from recent parturition and old uterine troubles. There was no proof of syphilis. She used eserine, and took various medicines, including iodine and arsenic, for a year, and then went to Guy's Hospital, where, under Mr. Higgen's care, she had continued the same local treatment and taken iodide of potassium and mercury. The symptoms in the

left eye are unaltered, except temporarily, by the eserine drops; the healthy skin affected by the morphea has become partially atrophic, and the hair on the affected area has nearly all fallen off. Latterly there have been threatenings of an onset of the same disease on the right side of the face and in the right eye, but it is not at present declared. During the course of the case there had been some eczema behind the ear and on the palm on the same side as the morphea. The authors pointed out that, whilst the morphea was strictly confined to territories supplied by the first and second divisions of the fifth nerve, the eye symptoms pointed clearly to affection of the branches of the third to the interior of the eyeball; and they observed that in this respect the case might be compared with those cases of herpes of the fifth in which the third or other motor nerves were also affected.—Mr. Higgins said there was a patch of morphea over the angle of the left scapula; in all other respects she was in the same condition now as when she first came under his care.—Dr. Hadden asked if there was any loss of sensation. He imagined there must be some diffuse spinal and cerebral change, as the disease was not limited to the face and eye, but affected the opposite scapula.—Mr. Nettleship replied that there was no general loss of sensibility, save over the large patch of morphea on the temple. Nothing suggested to his mind any central nerve disease.

The following cases were shown:—Congenital Deformity of Femur, by Mr. Morgan; Sclerema Neonatorum, by Dr. T. Barlow; Lateral Curvature of Spine, by Mr. B. Roth; Myxoedema, by Dr. Stephen Mackenzie.

Lingual Dermoid Cyst.—Stretching the Facial Nerve.—Spondylitis Deformans.—Epithelioma.—Nodes in Congenital Syphilis.—Infantile Hemiplegia.

An extra meeting of the Clinical Society of London was held on June 1st, Dr. Andrew Clark, President, in the chair. There was only a small attendance of members, but a large number of communications were read. At the close of the meeting the Society adjourned until October next.

The committee on Dr. Tyson's case of Leprosy reported that sections of a piece of skin removed from the lad showed the presence of the peculiar bacilli noticed by Dr. Thin and others in tuberculated leprosy.

Mr. Barker related a case of Large Sebaceous or Dermoid Cyst in the Tongue, removed by operation, with cure. The case was one of a woman, aged twenty-eight, who had first noticed pain and difficulty in swallowing seven years before. Soon after a swelling was observed exactly under the tongue in the middle line, and directly behind the symphysis menti. This had been increasing ever since. On admission into University College Hospital it pushed the mucous membrane forwards and upwards, so as to make an interval between the jaw and the root of the tongue of quite an inch broad. It also projected beneath the chin for about an inch and a quarter. The skin over it here was perfectly normal, and in no way attached to the tumour. The whole tongue was thrust much upwards, and its dorsum rested against the hard palate. The tumour was painless, and fluctuated over its whole surface; there was no trace of inflammation anywhere about it. On puncture with a grooved needle, typical sebaceous matter was obtained. On Aug. 12th, 1882, Mr. Barker removed the tumour by a straight incision in the middle line under the chin. The tough cyst was reached above the mylo-hyoid muscle, and lay here partially separating the genio-hyoidei. It

was easily separated from its bed, which lay almost entirely between the genio-hyo-glossi muscles, and reached quite up to the dorsum of the tongue, only covered by the tough mucous membrane of the latter. Blunt instruments and scissors were used, and hardly a trace of blood was lost, no vessels requiring to be secured, except one tiny twig, which was pinched. The wound, having been well cleansed with carbolic solution; the skin was brought together with four silver sutures, and the large cavity drained with a tube. The wound healed in a few days without any suppuration or reaction, and the patient left the hospital on the sixth day after operation. The cyst (shown), being removed entire, was found very tough and firm-walled. It measured 3 in. by 1½ in., and was somewhat uniform. Its contents were like porridge, with a faint, sour smell, and under the microscope were seen to be typical sebaceous material. Its wall was fibrous, lined by a thin, glistening membrane, leaving no doubt as to its nature. Mr. Barker stated that after careful search he had been able to collect only sixteen recorded cases of lingual tumours of the kind, exclusive of his own two. From an examination of these, it appears that these cysts may occupy three distinct situations in relation to the tongue:—(1) Between the genio-hyo-glossi muscles in the middle line; (2) they may be unilateral—that is, lie between the mylo-hyoid muscle and genio-hyo-glossus of one side; and (3) they may be bilateral, lying above the mylo-hyoid and below the genio-hyo-glossi of both sides. Their contents vary also very much, as also the age of the patients among whom they are met, although they appear to be, in a sense, congenital. Mr. Barker preferred complete enucleation, without opening the sac, as the easiest and safest operation. This may either be done from the mouth or by a median incision, as in the last of the author's two cases. The scar left by the last method is very trifling, as seen in the patient exhibited, and the ease and safety of the operation are greatly increased where larger cysts have to be removed.

Mr. R. J. Godlee read a paper on Cases of Stretching the Facial Nerve for Tic Convulsif. The first case was the conclusion of one reported in vol. xiv. of the Transactions of the Clinical Society, p. 44, by Dr. W. Allen Sturge and Mr. Godlee, that of a lady, aged seventy-two, in whom the operation had been performed for right-sided tic. The result was almost complete relief for nine months, when the spasm recommenced as the result of a sudden and severe nervous shock, and gradually regained all its former intensity. The patient remains in tolerably good health, but still suffers from some neuralgic pain in the face, principally in the right supra-orbital nerve, and at the top of the head, on the left side, at the seat of an old injury. She is unwilling to undergo any further operation. The next case was that of a man, aged thirty-six, who had suffered from bilateral tic for some years without assignable cause. There was no syphilis, and no source of reflex irritation, except some old carious stumps of teeth. It was made worse by exposure to cold and bright light and excitement. He had slight supra-orbital neuralgia on the left side. He was kept under observation for some months, and improved while perfect rest was maintained, but relapsed when allowed to go about. The left supra-orbital nerve was first divided subcutaneously without good effect, and subsequently the left, and afterwards the right, facials were stretched by the same method as in the former case. In both instances the twitching recommenced after three months, as the paralysis disappeared and returned as severely as before the operations. Arguments were adduced

in favor of the mischief in these cases being situated in the region of the medulla oblongata, and references were made to as many reported cases as the author could discover. It was shown that, though all of these had been reported at first as examples of success, in all (except in one reported by Mr. Southam, of Manchester, which remained quite well after two years) more or less return of the twitching had occurred. Some, however, according to reports carried up to the present time, remain to some extent improved. The total number of cases in the table amounted to thirteen. It was then urged, that if Mr. Southam's case did not exist, we should have to consider this chapter of surgical therapeutics closed, but that while it remained well there was still a certain amount of hope that the operation might be sometimes successful. It was lastly pointed out that the stretching of a small nerve on a hook acts differently from the stretching of a large nerve with the finger. In the latter class of cases the effect was probably either a loosening of the nerve from its sheath, or some influence on the nervous centre; in the former it caused a solution of continuity of the nerve, but with a certainty of union. The *modus operandi* was, therefore, probably not a profound effect upon the centre, as had been supposed, but merely the breaking of a bad habit, which must be taken for what it is worth.—Mr. H. Page thought the operation had been done oftener than might be inferred from Mr. Godlee's table. His colleague, Mr. Pye, stretched the left facial nerve and obtained relief for his patient for four months, but lately the spasms had returned after a severe fright. He himself had stretched the facial nerve for an obstinate case of incomplete facial paralysis, which had been attended with some very slight improvement. Dr. Braun had recently made observations on the effect of stretching the sciatic nerve, and he had found movements produced in very distant parts of the spinal cord. The President agreed with Mr. Page that the table was really incomplete. Mr. Hutchinson had stretched the facial nerve in a patient of his two years ago with complete relief. He thought that Mr. Godlee's paper was one of considerable value.

Mr. H. H. Clutton read notes of a case of Spondylitis Deformans. The patient, who had been exhibited at a previous meeting, was thirty years of age, and the subject of a severe form of ankylosis of the spinal column. In the family history there was nothing to indicate hereditary taint. In his previous history there was strong evidence of rheumatism affecting the joints. When nine years old he was confined to bed for rheumatism, which, with several intermissions, lasted for six months. It began in the metatarso-phalangeal joint of the right big toe. It then attacked the right knee, and finally the right hip. The latter joint had, he said, remained stiff ever since. Six years ago he had a painful foot, which the doctor called rheumatic gout. He had never had any venereal disease of any kind, and, beyond the attacks above described, had always had good health. Three years ago he first felt pain and stiffness in his neck, but they had caused him little inconvenience till the last six months. He can give no account of his back or chest, and is not aware that they are fixed and immovable. For the last three months his left shoulder has been stiff and painful, and he still occasionally suffers from rheumatic pains in the right hip. His present condition is one of almost complete ankylosis of the spinal column. He stands with the left leg advanced in front of the right, with the knees bent, and in a stooping posture. His spine presents one large dorsal curve, with the convexity backwards. The head is craned forwards, and the

chest sunken and depressed. The movements of the head are very much impaired, although not as yet completely destroyed. He cannot turn his head at all to the right, and only slightly to the left, the nose moving about an inch and a half from the median line. The lateral movements ordinarily obtainable in the cervical region are entirely absent. In raising and depressing the head, the chin only moves three inches. There is no movement whatever in the lower cervical vertebrae. This is very apparent on trying to make the patient bring his chin towards the sternum. On bending the whole body forwards, it is seen that the spinal column is quite rigid; there is no separation between the spinous process, or increase of curve. With the knees extended the tips of the index fingers just touch the patella, and this movement appears to be effected by the hip-joints. The respiratory movements are entirely abdominal. On the deepest inspiration there may be some slight expansion, but there is no elevation of the ribs. His height is now 5 ft. 2 in., and he is quite sure that some years ago he was 5 ft. 5½ in. As to other osteo-arthritis changes, the patient has several creaking-joints and distinct "lip-growths" in both shoulders and big-toe joints. He has also distinct limitation of movement in the left shoulder. The right great trochanter is larger than the left, and tender on pressure. All the other joints except those named seemed perfectly healthy. Such an extensive and severe form of ankylosis of the spine, with or without osteo-arthritis changes elsewhere in the body, was a rare condition in a man thirty years of age, and it was on this account Mr. Clutton brought him before the Society. A similar case was shown at this Society by Dr. Allen Sturge, and is recorded in the Clin. Soc. Trans., vol. xii.

Dr. Lediard also contributed notes of a case of Spondylitis Deformans and Osteitis Deformans. The patient was a miner, aged fifty-eight, from Cumberland, who had suffered from repeated attacks of pain in the spine, and rheumatic affection of the joints, and of late years stiffness of the spine and head, so that the body was bent forwards in a stooping posture. The spine was absolutely ankylosed except for slight movement in the neck, and the head was firmly fixed to the spine. Several joints presented chronic rheumatoid arthritis changes; there was no movement of the chest walls, respiration being entirely diaphragmatic. The femora were curved forwards and outwards, and the shafts, somewhat massive, suggesting the disease known as osteitis deformans in possibly an early stage. The skull and clavicle were, however, unaltered.—Dr. Dyce Duckworth said that if the changes in spondylitis deformans were the same as those in osteo-arthritis, it was remarkable that the spine was so rarely affected. He believed Mr. Hutchinson had said that gonorrhoeal rheumatism was often the starting-point of spondylitis. The most interesting cases were those occurring in young people.—Mr. Clutton stated that his patient denied ever having had gonorrhoea.

Mr. George Lawson related the history of two cases of Epithelioma which had occurred on old Cicatrices, and which he had removed. In the first case, the patient, a pale, anæmic woman, aged thirty-eight, had lost, in childhood, the sight of both eyes, except the bare perception of light, from an ulcerative inflammation, probably diphtheritic, and which had caused complete adhesion of the upper and lower eyelids of each eye to the globe. The patient was admitted into the Middlesex Hospital in May, 1881, and the growth first commenced in the previous September. It sprang from the cicatricial tissue which united the left lower eyelid to the globe, and steadily increased

until it obtained the dimensions shown in a drawing, the whole front of the eye being occupied by it. Mr. Lawson removed the growth and the eye. Two years have now elapsed since the operation was performed, and there has been no recurrence. In the second case, the patient, a strongly-built man, aged thirty, was admitted into the Middlesex Hospital in March, 1881, with an epithelioma of the left thigh, which occupied the greater part of a large cicatrix. Twenty years previously his left thigh was crushed by a heavy cart passing over it, which caused great laceration of the skin and muscles. He was seven months in the Aylesbury Hospital, and when he was discharged there was still an unhealed superficial wound of about the size of a small saucer. He then went to work as a farm laborer, but the wound never healed. Two years and a half before his admission into the Middlesex the wound took on a new action. It began to spread rapidly, the granulations became large and fungoid, and it occasionally bled. On admission there was found an epitheliomatous ulcer measuring seven inches and a half by eight inches. Mr. Lawson amputated the thigh just below the trochanters, and although two years have elapsed there has been no recurrence of the disease. Mr. Lawson remarked that the cicatrices which seemed specially prone to epithelioma were the tight cicatrices, such as are caused by a great destruction of skin, and those cicatrices upon which there is a constant tension. Both the cases, he said, tended to show that if epithelioma can be completely excised before it has affected the lymphatic glands, it is the form of cancer which is the most amenable to treatment; whilst experience has taught us that after the lymphatic glands are invaded, epithelioma is the most formidable and irremediable of all the cancers.—Mr. Godlee asked if the epithelioma sprang from the middle or the edge of the scar. He referred to a case in which cancer started in the centre of a lupus scar.—Mr. Lawson said that the unhealed part of the wound became a fungating epithelioma.—Mr. Haward said these cases pointed to the local origin of cancer. He referred to a case of an unhealed burn on a leg which had remained in much the same state for twelve years. Then it began to be painful and fungate, all attempts at healing failed, and eventually the leg was amputated and the growth was found to be epitheliomatous. There was no history of cancer in the family. There had been no recurrence of the disease after seven to eight years. There were other such cases of long unhealed sores becoming cancerous which had been completely cured by excision.—Mr. A. Barker said the case was interesting as showing the influence of local irritation in causing epithelioma; this was specially found in cases of cancer of the tongue.—Mr. Pearce Gould referred to a case of a woman in whom epithelioma developed at the edge of a scar on the thigh caused by a burn thirty years previously, and to the case of a man who had received a charge of shot in the leg several years before in whom epithelioma developed in and around unhealed sinuses. Such cases showed the close resemblance of the less malignant forms of epithelioma to rodent ulcer which Mr. Moore had shown to start very frequently in old scars.—The President asked if Mr. Lawson had found syphilitic plaques in the tongue precede epithelioma, and how irritation led to cancer.—Mr. Lawson replied that syphilitic tongues were more subject to cancer than others. These cases of epithelioma were very manageable in their early stage, but utterly beyond control in their later stage. There were many instances of local irritation producing cancer, but he was unable to explain how it did this.

Dr. Radcliffe Crocker described the case of a girl, aged twelve, with Nodes from Congenital Syphilis. The patient had been shown at a previous meeting. She had enteric fever five months before she came under notice, and during convalescence two nodes appeared on the forehead, one on each side of the median line; there was another tumour in the right orbit, softer than the nodes and movable. There was no corroborative evidence of syphilis about the girl except the two upper central incisors, both of which were notched, and one was slightly pegged. No history of infantile syphilis could be obtained, and the mother and the other children were apparently quite healthy; but eventually it was ascertained that the patient was a child by a previous husband, who died soon after marriage, had lived a dissipated life, and was never well, but resented inquiries into the cause of his ill-health. The patient was put under iodide of potassium, and when last seen the softer tumour had gone, and both the nodes were softer and much smaller, and the improvement in the general health of the patient was very striking. Dr. Crocker remarked that the case corroborated Sir James Paget's observation that typhoid fever often aided in the discovery of constitutional taint, and also Mr. Hutchinson's observations on the value of the notched and pegged incisor teeth as evidence of congenital syphilis.

Dr. Frederick Taylor read a paper on the case of Infantile Hemiplegia with unusual Reflex Phenomena, shown at the last meeting of the Society. The patient was a child, aged five, who was seized with convulsions at twelve months old. This condition lasted two hours, and was followed by weakness of all the extremities. In a few days the right arm began to move, and the right leg, but the left limbs remained paralyzed. Gradually rigidity developed, and with it the curious reflex irritability to be described. The child was fat and well, commonly semi-recumbent with both legs semiflexed and rigid, the left arm flexed at all joints and rigid. This arm is scarcely used, but the right freely and well. Both legs can be moved, but not completely flexed or extended. The right is less rigid than the left. The child cannot sit up in bed, nor stand upright, nor walk. The left arm and leg are nearly two inches shorter than the right arm and leg respectively. On making a sudden noise near the patient the left arm is quickly thrown out at right angles to the body, the elbow, wrist, and fingers are extended, the face assumes a puzzled expression, and the legs undergo moderate extension. The condition of spasm remains for about thirty seconds, then slowly relaxes. The same reflex contractions are brought about by shocks affecting the surface of the body, as a blow on the crib or a tap on the head. Vision appears to be good, but there is disseminated choroiditis in very small patches in both eyes. He is lively, fairly intelligent, and can talk. He passes feces and urine involuntarily. But for the choroiditis there is no conclusive evidence of congenital syphilis. He has been four months treated with iodide of potassium and mercury, but shows no material improvement. Dr. Taylor thought the case was allied to those of infantile hemiplegia with spastic or choreic phenomena occurring afterwards. Though not strictly unilateral the disease on the left side was obviously of cerebral origin, and that on the right side must be explained by a second lesion, or more likely by a single lesion crossing the middle line. The mode of origin suggested obstruction of a vessel with syphilis as a possible antecedent. Its early occurrence and the deficient growth of the left limbs rendered it probable that asymmetry of the brain also co-existed.

MEDICAL SOCIETY OF LONDON.

Dysentery and Liver Abscess.

At a meeting of this Society on April 30th, the President, Sir Joseph Fayrer, read a paper on *Dysentery and Liver Abscess*.—In the discussion which followed the reading of the paper Dr. N. Chevers said that recovery is probably rare in cases of pyæmic abscess of the liver, but as the peritoneum is not extensively involved the symptoms may be masked. He had found that those cases of dysentery which did not benefit by ipecacuanha always had liver disease, and recalled a case in point where the liver was full of linear cicatrices, such as would result from the healing of multiple pyæmic abscesses. His general conclusions from the treatment of a large number of cases similar to that recorded by Sir J. Fayrer were, when heavy and severe pain comes on in the right side in dysentery or malaria, to exhibit moderate doses of ipecacuanha, a purgative if necessary, large mustard poultices, and then blisters. With such measures he never saw hepatic abscess develop. If the abscess result from the absorption of septic matter, with embolism or thrombosis, how is it relieved by ipecacuanha or counter-irritation? He thought it began with congestion, and later thrombosis might occur. He referred to the case of a Bengal civilian, who was attacked by violent pain at the base of the right lung; pleurisy and pneumonia were diagnosed, and he died. On post-mortem examination a large solitary abscess was found, so old that its sac was cretaceous; ulceration took place around it and had caused the pulmonary inflammation. Another case was one of a fellow student of his at Guy's Hospital, of strumous aspect. He was attacked with agonizing pain, but travelled a distance of two hundred miles; and some weeks later an abscess was evacuated through the lung. He expectorated almost pure bile. When he died only a pulmonary abscess was found.—Surgeon-General Hunter thought it well to dissociate pyæmic abscess from tropical abscess. The former is a part of a general condition; the latter a local disease. The abscess may exist with symptoms of very minor importance. Dysentery may occur without abscess, and hepatic abscess without dysentery. Abscess of the liver in India occurs as follows:—The man has had malaria, or lived intemperately, or both. He gets out of condition, loses flesh, has "hepatic" dyspepsia; then a localized swelling over the liver is noticed, and, if contracted, it will burst in one or other direction. The abscess may be single, more often multiple. He mentioned a case of severe abscesses in a man who had never had dysentery, and had been in Egypt six months, but drinking hard. Exploratory puncture of the liver is harmless, and may give great relief. He did not like the aspirator for large superficial abscesses, but preferred a free opening with antiseptic drainage.—Dr. S. MacKenzie supported Budd's view of the pyæmic causation of many hepatic abscesses, but in phthisis and typhoid fever abscess of the liver is very rare, so that something more than ulceration of the intestine is required. Abscess of the liver may occur from (1) venous embolism from disease of viscera opening into portal vein; (2) in connection with disease of the hepatic area as in head injury, as pointed out by Pott; or (3) arterial embolism; (4) suppurating hydatid; (5) traumatic—very rare; (6) large abscesses without any intestinal disease. He had seen several cases of liver abscess discharge through the lung; reddish pus is often expectorated for weeks and months; very often the patient dies from the lung disease.—Dr. Drewitt

said empyema was quite analogous to abscess of the liver in regard to treatment.—Dr. Dyce Duckworth said that it was of great importance to regard closely the constitution and temperament of the people in whom this disease occurs. The personal element must not be left out of the question. Dr. Ewart had said that subjects of dysentery would become tubercular in this country.—Dr. Dickson had seen dysentery in many parts of the world, and amongst these cases had met with several of liver abscess. In China and in naval practice abscess is not common in cases of dysentery. On the coast of Africa and also on the Mediterranean abscess is rare, although malarial dysentery is common. Again, dysentery was common here 200 years ago, but he thought that abscess had not been much noted. Dr. Ward thought that liver abscess and dysentery were the result of the same cause.—Dr. Sanderson had had experience of native troops only, and had not had many cases of liver abscess, but he had no opportunities for post-mortem examinations on sepoy. Perhaps their immunity from abscess had some relation to their eating less animal food or drinking less alcohol.—Dr. Dowse referred to Dr. Hammond's cases of liver abscess in hypochondriasis in support of the existence of such abscess without symptoms.—Sir Joseph Fayrer deferred his reply to some future occasion. He then stated that the next meeting would be held in the new rooms under great advantages, and thanked the Fellows for their kindness in attending the meetings under the great difficulties entailed by the building operations. He announced that H. R. H. the Prince of Wales had signified his intention of attending the Society's conversazione.

OPHTHALMOLOGICAL SOCIETY OF THE UNITED KINGDOM.

Eye Symptoms in Spinal Disease.

A MEETING of this Society was held on June 14th. Mr. W. Bowman, F.R.S., President, in the chair. A discussion upon eye symptoms in diseases of the spinal cord was opened by Dr. Gowers.

Dr. Hughlings-Jackson, after remarking on the great excellence of the paper, spoke of the great complexity of *tabes dorsalis*. The symptoms were most various, joint affections, gastric crises, several very different morbid affections of the eyes, bladder symptoms, etc. Of the so-called typical symptoms, one or more might be absent; ataxy was often absent; with ataxy, the knee-jerks might be present. In one case of seventeen years' duration, the Argyll-Robertson symptom was not found. Some of the so-called typical symptoms were discovered in other diseases. The commonest pupillary condition was seen in some cases of general paresis. The knee-jerks were absent in many different morbid conditions, one of the most important of them being diptherial paralysis, a disease which, superficially regarded, had sometimes a great likeness to locomotor ataxy. There were degrees of some, at least, of the symptoms; no ataxy, degrees of ataxy, and, so to speak, a degree beyond ataxy, in inability to walk at all. If there were not degrees of pupillary conditions, there were various such conditions. The width of the symptomatology was exceedingly different in different cases. There might be the Argyll-Robertson phenomenon with no other definite nervous symptoms, and when so, the nature of the case, beyond perhaps the vague diagnosis of nerve degeneration, could not be concluded upon. A case of *tabes* without ataxy might present a far wider symptomatology than one with ataxy. Dr.

Hughlings-Jackson, admitting the frequency of eye symptoms with disease of the spinal cord, knew of none from lesion of it, excepting when that lesion was in the cilio-spinal region, as, for example, in a section of half the cord from a stab with a knife (contractions of the pupil on the same side, and narrowing of the ocular aperture). To statistics of optic atrophy, in its relation to other tabetic symptoms, he could offer nothing definite, one reason being that cases of morbid eye affections were sent to him because he was known to be specially interested in them. He urged that the Argyll-Robertson condition was often found in cases of optic atrophy (tabetic), not only when sight was slightly impaired, but when there was bare perception of light; in one case he had found it when the loss of sight was absolute. The pupils enlarge when the patient "makes believe" to look at the clouds, and contract when he makes believe to look at his fingers held near him. On the other hand, with considerable impairment of sight, the pupils may remain contractile to light. To illustrate the varying width of association of optic atrophy with other tabetic symptoms, he mentioned five cases. 1. Atrophy of one optic nerve and then of the other (green appearing grey, and red reddish-brown), pupils acting to light, gait good, jerks present; in short, no other symptoms except lightning pains. 2. Optic atrophy with the Argyll-Robertson conditions, and without pains; and for the rest (saying nothing, however, of color-perception, which was not tested) like the former case. 3. Like 2, but with pains also. 4. Optic atrophy (blind eight years), Argyll-Robertson condition, gait good, no knee-jerks. 5. A much more rapid case; pains, one year blindness complete except for bare perception of light, in six months; could only just stand (loss of sight, no doubt, contributing to this disability); no knee-jerks. Dr. Hughlings-Jackson then spoke of cases of double optic neuritis, with absent knee-jerks. A woman; bare perception of light, reeling gait, no knee-jerks, who, after mercurial inunction and iodide of potassium, got well, except that, when last seen, she had no return of the knee-jerks. A girl, seen with Mr. Bowman; she had double optic neuritis, reeling gait, no knee-jerks then or after; later, right hemiplegia and aphasia; no necropsy. A man, who died with tumour of the left cerebral hemisphere, had aphasia and right hemiplegia; both knee-jerks present at first, both lost later; no morbid changes found in spinal cord by Dr. James Anderson. Dr. Hughlings-Jackson had seen double optic neuritis with absent knee-jerks, and no, at any rate, no other, localizing symptoms. He had nothing to say as to the nature of any associations of optic neuritis with any morbid conditions answering to those of the knee-jerks. The jerks were present in some cases of tumour of the cerebellum, with double optic neuritis in one case of a lateral lobe, in another of the middle lobe (necropsy). He then spoke of diphtherial paralysis. He had been incorrectly reported to have said that this disease was owing to a morbid affection of the sympathetic system. What he ought to have said—all that he really holds—is that the ocular, the palatal, and the rarer circulatory symptoms (great slowness of pulse) of this disease, are morbid affections of parts supplied through ganglia of the sympathetic; he believes the spinal cord, as well as higher parts of the nervous system, to be morbidly affected in this disease. He had not seen a case of so-called diphtherial amaurosis in a stage when the paralysis of the ciliary muscle was complete; in some cases, where accommodation was only weak, he thought the pupils acted well to light, whilst action of them during accommodation was at least imperfect. In one case, the

knee-jerks did not reappear until one year after all the symptoms of diphtherial paralysis had gone. Dr. Hughlings-Jackson then went on to speak, by stating cases, of the very different abnormal intra-ocular motor conditions met with in tabes, or existing along with one or more of the so-called typical symptoms of this morbid affection. He spoke of the commonest, the well-known Argyll-Robertson conditions, only incidentally. 1. Sudden and complete loss of both pupillary activities and of accommodation on but one side; gait good; no knee-jerks; there had been lightning pains four or five years; the other eye, carefully examined for the Argyll-Robertson condition, was normal. 2. The same condition as in the last case, except that the so-called good eye presented the Argyll-Robertson symptom. This patient, a healthy-looking intelligent sea-captain, had no other symptoms, mental or physical; hence the feature of his case could only be guessed at. 3. Argyll-Robertson condition on but one side; ataxy, lightning pains, no knee-jerks. 4. A woman; loss of action of one pupil to light and during accommodation, accommodation itself being absolutely perfect (examined by Mr. Couper); the pupil of the other eye was normal; that eye had all her life been slightly defective; no other symptoms of any sort were discoverable, except the most significant one of absent knee-jerks. 5. The same ocular condition on both sides (examined by Mr. Couper); ataxy, lightning pains, no knee-jerks. 6. The same ocular conditions, except that accommodation was slightly weaker than usual at the patient's age (examined by Mr. Nettleship); gastric crises, ataxy, lightning pains, no knee-jerks. 7. Both pupils acting in no way, accommodation of each eye good; ophthalmoplegia externa; the only further tabetic symptom was absence of one knee-jerk and nearly loss of the other. Dr. Hughlings-Jackson again remarked on the complexity of tabes dorsalis, adding the expression of his belief that Dr. Gowers's able paper would help us greatly in precise and methodical investigation of this morbid affection.

A paper on Ocular Symptoms occurring in General Paralysis of the Insane, by Mr. W. Bevan Lewis, was read by the Secretary. By the systematic examination of a large number of cases, the author has been led to the following conclusions: (1) That a loss of reflex dilatation of the pupil to sensory stimulation occurred in the greater number of cases of general paralysis of the insane. (2) That, next to this condition, the most frequent accompaniment of the disease was loss of pupillary reaction to light (reflex iridoplegia). (3) That in 23 per cent. of the cases the movements on accommodation were completely lost, and that (4) in a few cases cycloplegia was associated with this. (5) That ophthalmoplegia interna was found only in advanced stages of the disease; in one case it appeared to commence as reflex iridoplegia. (6) That, with the exception of one case, reflex iridoplegia was always present when the movements on accommodation were impaired or lost. (7) That spinal symptoms (such as absence of patella reflex) were by no means especially associated with the more grave ocular troubles. Finally, Mr. Bevan Lewis concluded, judging from the nature and progress of the disease, its duration, the history of cases in the earlier stages, and the condition of the paralytic in the more advanced stage, that the sequence of phenomena occurring in the iris in this disease was this, that there was, first of all, loss of reflex dilatation to cutaneous stimulation; that, next, the action to light was lost (reflex iridoplegia); and that, in the final stage, ophthalmoplegia interna was developed, and became in the end complete.

Dr. Savage, who spoke in response to a call

from the President, said that he was not prepared to bring forward any statistics bearing on the question. He believed that the examination of the optic disc would lead to a considerable increase in our knowledge with regard to general paralysis of the insane. When, now a good many years ago, he had first begun to examine patients suffering from this disease with the ophthalmoscope, the results had been negative or unsatisfactory. In conjunction with Mr. Henry Power he had made careful observations on a large number of these patients with the sphygmograph and the ophthalmoscope, but the results had been so purely negative that it had not appeared worth while to make any permanent record of them. In recent years, however, he had gradually come to appreciate certain changes which occurred in the optic discs, not of all, but of a certain number of patients suffering from general paralysis. In one class of these patients tabetic symptoms were prominent, and sometimes preceded the other symptoms of the disease by many years; for instance, in one case tabes had been in existence for ten years before the development of general paralysis led to the admission of the patient into Bethlem Hospital. In such cases as these changes in the optic disc were commonly found; he had, however, only recently learnt that these changes were not confined to the patients who presented tabetic symptoms, but that they occurred also in another class of patients—those who presented symptoms of lateral sclerosis. In this connection the question arose whether this lateral sclerosis was secondary to degeneration of the motor tracts in the brain. He had met with a few cases of general paralysis of the insane occurring in young single men of steady habits, where lateral sclerosis developed secondarily to intellectual symptoms, and in these cases there were changes in the optic discs. It was now generally recognized that "general paralysis" was a wide term, embracing a number of separable conditions; in making this subdivision, a careful attention to alterations in the optic discs and in the reflex phenomena would be of great assistance.

At this stage the debate was adjourned until the following evening.

Adjourned Debate on Eye Symptoms in Spinal Disease.

The debate on eye symptoms in spinal disease was continued, Mr. R. Brudenell Carter in the chair.

Dr. Walter Edmunds detailed a case. The patient was a man, aged fifty-seven, who had had syphilis nine years before. He remained well till three years ago, when he fell from his horse and hurt his neck; three months later he again fell from his horse, and thought that this was due to an attack of unconsciousness. Soon after this, he one day had a sudden attack of blindness, without any giddiness, headache, loss of consciousness, or vomiting; the attack lasted fifteen minutes. Subsequently, he had three attacks of vomiting. When he came under observation his gait was awkward, but not ataxic. Both pupils were fixed to light; the left pupil acted on accommodation, the right did so to a less extent. The chief point of interest in the case was the attack of complete temporary blindness.

Mr. J. B. Lawford read notes of seven cases of General Paralysis of the Insane in which Optic Atrophy occurred. In five out of the seven there were symptoms of spinal sclerosis; in one, tabetic; in the other, lateral sclerosis. Of twenty-two cases of general paralysis recently examined at

Bethlem Hospital, Mr. Lawford had found optic atrophy in three, in all of which spinal symptoms were present. Microscopic sections and drawings of the optic nerves, chiasma, and tracts of one of the cases were exhibited.

Mr. R. Marcus Gunn said he proposed to offer very brief replies to some of the questions Dr. Gowers had put in his memoranda. Out of eighteen cases of optic atrophy that had been admitted into Moorfields during his term of office, two had locomotor ataxy, and three others were suspected of it. As regarded the date at which the atrophy supervened, out of nine cases of ataxy, seven had optic atrophy, and in all it appeared during the first stage. In five of these cases the changes were more marked in the left eye, in two in the right eye; in three cases the changes were known to have commenced in the left eye. There might sometimes be a temporary arrest, and even slight improvement in the atrophy; three instances of this were given. In conclusion, he alluded to two cases presenting some features of interest, namely:—1. A man, aged thirty-nine, with locomotor ataxy and optic atrophy, but not much affection of sight, his vision being 20-20ths in one eye and 20-30ths in the other, which had more lately, however, deteriorated to 20-40ths. 2. A woman, aged forty-nine, who had in early life rheumatic fever, then small-pox, and afterwards intermittent fever; then paralysis came on, commencing in one leg, then going to the opposite arm; gradually becoming general and complete, it lasted two years. For many years she had had exophthalmic goitre; the prominence of the eyes was gradually diminishing. She appeared to have had an epileptic fit. About a year ago it was noted that the pupils were small and did not act to light, but acted to accommodation; there was paresis of right external rectus, the knee-jerks were diminished, and slight ptosis on left side was noted. More recently it was found that the paralysis of the ocular muscles had disappeared, the knee-jerk was absent, and the pupils still acted to light, but not to accommodation.

Dr. Mahomed thought that it was proper to remember that in dealing with the diseases of the nervous system, we were dealing with the diseases of one organ and of one tissue; it was everywhere continuous, and its diseases were similarly, in many cases, continuous—that is, uniformly distributed throughout it. In observing the changes in the optic disc, or in testing the intraocular reflex phenomena, we might be only discovering, in the most susceptible part of the system, disorder which might exist in a lesser degree in all the coarser reflex actions. He thought there was a tendency to attach too much importance to individual symptoms, and to attribute to them a greater pathognomonic significance than they deserved. Dr. Mahomed concluded by quoting several cases in support of his contention that too much importance ought not to be attached to alteration in the knee-jerk, to ankle-clonus, or to nystagmus, as evidence of structural disease.

Dr. Seymour J. Sharkey contributed an account of three cases. The first was that of a woman who, at the age of twenty-nine, began to suffer from giddiness, thickness of speech, trembling (on the right side chiefly), and severe headache. Three months later the case came under the care of Mr. Hulke, at the Royal London Ophthalmic Hospital, for optic neuritis and defective sight in the left eye. She came under the care of Dr. Sharkey when thirty-four years of age. There was then incomplete atrophy of both optic discs, and distinct symptoms of disseminated sclerosis. The second case was that of a man who came under care when

twenty-two years of age. The right disc was then hazy and slightly oedematous. A year later he was admitted into St. Thomas's Hospital, under the care of Mr. Nettleship, and the right disc was found to have passed into a state of grey atrophy. The left disc could be only imperfectly seen, owing to old corneal opacities. Three years later, when twenty-six years old, he came under Dr. Sharkey's care with characteristic symptoms of disseminated sclerosis. The third case was that of a man aged forty-two, who presented symptoms of the same disease. These symptoms were said to have been present for about fifteen years, but his sight had only been failing for about twelve months. His vision was 20-70ths, and the discs were slightly pale and misty all over, the borders being nowhere quite clear. Vision subsequently slightly improved.

Mr. Nettleship made some observations on some of the points relating to optic atrophy in Dr. Gowers's address. He thought there were clinical reasons for believing that optic nerve-changes in locomotor ataxy began at the disc, not in the trunk of the nerve or optic tract; he had seen no unequivocal cases of spinal disease in which sight failed before ophthalmoscopic changes became apparent, whilst it was commonly observed, on the other hand, that the appearances of atrophy were more pronounced than the condition of the sight would lead us to expect. Of seventy-two patients under his care with progressive atrophy of the optic nerves, thirty-six were undoubtedly tabetic, eight had symptoms of mixed spinal and cerebral disease (allied to general paralysis), seven had some other forms of chronic spinal disease, not ataxy, eight had, besides optic atrophy, reflex iridoplegia ("spinal pupils"), but no other symptoms of disease of cord or brain; in the remaining thirteen there was no proof of disease of the nervous system, but in some of these the notes were incomplete. He had been struck with the rarity of the complete absence of spinal symptoms in progressive atrophy. Alluding to the mode of failure of vision in progressive atrophy, he pointed out that the field of vision is often invaded in a precisely symmetrical manner in the two eyes, although at any given time one eye is usually worse than the other. He had seen only two or three cases in which one eye became quite blind before the other began to fail.

Mr. Brudenell Carter said that the papers read had added much to the wealth of the material placed before the Society on the previous evening, but they served also to show the great complexity of the problems involved. It had not been his intention to take part in the discussion, but he would venture to say that all practitioners would be grateful to those who could give a clue to the value of the symptoms in the class of cases under consideration. It often happened that a patient with some impairment of walking power, and some optic atrophy, desired a prognosis; but it was most difficult to know whether the case was one of progressive spinal disease or not. He had attached some importance to the knee-reflex as a guide in this matter, but had not always found it trustworthy. Again, some cases came with optic atrophy and no other symptoms, as in the case of a sergeant who had been nineteen years in the army and had enjoyed perfect health, but for some months had been rapidly losing his sight, which improved markedly under hypodermic injection of strychnine. Would that man become ataxic? The occurrence of such cases made one grateful for some hint which could be utilized in daily work.

Mr. McHardy referred to a case which was unique in his experience. It was a case of dis-

seminated sclerosis in a young woman. The right eye showed no ophthalmoscopic changes, and vision was slightly below the normal. In the left eye there was typical retinitis pigmentosa with atrophy of the disc.

Dr. Gowers said that the very interesting papers were valuable contributions to our knowledge of the subject, but the discussion had been so slightly controversial that it left him but little to reply. Mr. Gunn's case of Graves's disease was one of great interest and complexity; it was also interesting as an instance of complete loss of the reflex action of the pupils to light preceding loss of the knee-jerk. Dr. Mahomed's general principles were unquestionably of great importance, and should be borne in view; but he (Dr. Gowers) had often been impressed with the opposite fact, in the remarkable way in which the nervous system suffers in part. Nothing, for instance, is more remarkable than that the posterior columns of the cord should be absolutely destroyed, whilst other parts exhibit no visible change. A definite diagnosis was hardly possible in Dr. Mahomed's case of optic atrophy with polyuria; the only symptom of tabes present in that case was pain. The occurrence of severe headache at the time of onset of the loss of sight suggested the possibility of the case being one of tumour just above the chiasma, a situation in which he remembered a tumour occurring that ran a very chronic course, and one in which polyuria was, he thought, also present. At the same time that would not explain the pains. It certainly was very unusual to have pains in the limbs from tabes of long duration, and not to have the knee-jerk reduced. Dr. Mahomed had alluded to the occasional absence of knee-jerk under normal conditions. Berger found it so absent in about 2 per cent.; and he (Dr. Gowers) mentioned several cases in which he could not detect it in his paper read before the Royal Medical and Chirurgical Society in 1879. But from that time to this he had never found it absent in health. There is a great fallacy in regard to the failure to elicit the knee-jerk; it very often cannot be obtained because the patient does not perfectly relax the flexors of the knee-joint, and if these muscles are not relaxed the jerk does not occur. This was particularly liable to arise in hysterical subjects, and hence the statement that the jerk is absent in hysterical paraplegia. The fallacy can be detected by placing the fingers on the flexor tendons and often obviated by causing the patient to sit upon the edge of a table. There was also a fallacy to guard against in testing the pupillary reaction to light, owing to the patient involuntarily accommodating to the light. He had been told of a case where the pupils did not react to artificial light, but did to daylight; probably this was due to the patient accommodating to the former. Dr. Sharkey's case of disseminated sclerosis was very interesting. Sight is sometimes lost, not simple atrophy, but because of sclerosis in the optic tract. The case referred to by Mr. Nettleship was very complex, because the nature of the lesion was uncertain. The spinal affection ensued upon malaria, and the symptoms were a combination of paralysis and ataxy; the loss of sight being probably due to the same cause as those symptoms. What is required is evidence of optic atrophy following an acute spinal lesion. Mr. Nettleship's statistics were of great value, being the most carefully compiled facts upon the question that have yet been made, and it is to be hoped that other ophthalmic surgeons will be stimulated to a similar research. Such facts bearing on the relation of optic atrophy to spinal diseases and to spinal symptoms should go far to settle the question. In the other case read by Mr. Nettleship, he thought

that the homonymous hemiopia was certainly accidental, and not connected with the morbid process of ataxy.

OBSTETRICAL SOCIETY OF LONDON.

A MEETING of this Society was held on June 6th, Dr. Gervis, President, in the chair.

Sarcoma of Ovary.—Dr. Galabin (for Dr. Elder) showed a Tumour of the Right Ovary having the microscopical characters of spindle-celled sarcoma, which had been removed from a woman aged fifty-five.

Anteflexion with Hypertrophy of Uterus.—Dr. Graily Hewitt (with Mr. A. Q. Silcock) exhibited a specimen of general and considerable Congestive Hypertrophy of the Uterus, with Acute Anteflexion and an Ovarian Cyst. The patient was aged forty, and sterile. The enlarged uterus nearly filled the pelvis; it was adherent on all sides, and acutely anteflexed. It weighed twenty ounces. There was a kind of dilatation of its cavity just above the angle of flexion. There was no evidence of separate fibroid formation, but it was a symmetrical hypertrophy of the whole uterus. No doubt the enlargement had existed for years, bringing about interference with the circulation in the uterus and pelvis generally. Dr. Graily Hewitt had seen cases analogous to this during life, but the large size of the uterus in this case rendered it almost unique.

Dr. Hewitt also showed an acutely Anteflexed Uterus from University College Museum. This uterus was in miniature very like the large specimen.—Dr. Robert Barnes had recognized cases of this kind clinically, and treated them successfully by the use for several months of iodine injections (one in eight). The iodine passed by osmosis through the body of the uterus, checking growth, promoting absorption of the hyperplastic tissue, and thus gradually reduced the uterus to the normal size, and effected a complete cure. He had in one case seen iodism produced, proving that the iodine went through the uterine wall.—The President asked where Dr. Hewitt drew the line between congestive hypertrophy and myo-fibromatous growth. The naked-eye appearances of the specimen closely resembled those of a fibroid.—Dr. Herman pointed out that in the second specimen slight dilatation of the uterine cavity was produced by the way in which the specimen was mounted.—Mr. Lawson Tait thought that if the case had come under his care he would have regarded it as an ordinary uterine myoma. The presence of ovarian cysts was important; for he thought that if they had been removed, the uterine tumour would have been cured.—Dr. Henry Bennet could testify to the value of iodine in chronic inflammation, with hypertrophy, of the cervix, extending or not to the body, of the uterus. Iodine applied to the skin left no permanent marks. He applied iodine solutions freely to the cervical canal, but did not inject them into the uterine cavity. The cavity of the body was separated from that of the cervix by a sphincter, which was closed in health. The injection of fluids by a syringe, the nozzle of which passed beyond the sphincter, was not free from risk. He had had one case of fatal peritonitis, and had repeatedly seen serious symptoms follow it, probably from the fluid passing through the Fallopian tube into the abdominal cavity.—Dr. Murray did not think injecting the uterine cavity was free from risk. He had seen instant pain and subsequent inflammation follow it; and the late Dr. Tyler Smith had mentioned to him a similar case.

Adhesion of Polypus to Vaginal Wall.—Dr. Potter showed a Polypus, the size of a small hen's egg,

growing from the body of the uterus by a short thick pedicle, and inseparably fixed by adhesion to the vaginal wall.

Pyo-salpinx.—Mr. Lawson Tait showed specimens of Pyo-salpinx removed from two patients. In one the cause was not known, and the symptoms had only lasted a few weeks. In the other the symptoms, which were constant pain, aggravated by menstruation and marital intercourse, followed confinement, and had lasted ten years. Both patients were recovering.

Mr. Knowsley Thornton showed large double Pyo-salpinx, one tube containing half a pint of pus, removed from a single woman, aged thirty. The ovaries were left. The patient was doing well.

Myxomatous Degeneration of Uterine Fibroid.—Dr. Godson exhibited a Tumour removed from a patient aged sixty-one, the upper part of which, attached to the anterior uterine wall, presented the characters of an ordinary sloughing fibro-myoma, while the lower part was myxomatous. He thought this kind of degeneration of fibroid was very rare.

A Case of Acute Gangrene of the Vulva in an Adult, with Remarks.—This paper, by Dr. Herman, was then read. The case related was one of acute gangrene of the skin of both labia, the perineum, and margin of the anus, and the mucous membrane of the lower part of the vagina and urethra, occurring in a patient aged thirty-seven, without clearly discoverable cause, the gangrene being apparently the result of acute inflammation. The author had collected all the published cases that he could find of similar gangrene of the vulva in adults occurring independently of venereal phagedæna. He found they might be divided into four classes. 1. Those occurring in patients suffering from acute diseases—viz., the specific fevers and cholera. 2. Epidemic puerperal gangrene, which had occurred in hospitals only, beginning as isolated round or oval sloughs on the inner surface of the labia, the process usually stopping with the separation of the sloughs, though sometimes going on to extensive destruction of the parts. 3. Acute gangrene, occurring independently of contagion and beginning with acute inflammation of the external genitals more superficial than noma, and not spreading like erysipelas. 4. Spreading gangrenous cellulito-cutaneous erysipelas. The author did not think there were grounds for a positive conclusion as to whether the differences between these classes were essential differences in the morbid process or merely minor differences due to the circumstances of origin, but he thought probably the latter was the case.—The President thanked Dr. Herman for his paper, and remarked on the rarity of the malady described.—Dr. Cleveland suggested that the gangrene in Dr. Herman's case might have been caused by a chill, occurring in a woman ill clad and of broken-down constitution.—Dr. Fenton Jones suggested that the gangrene might have arisen from local septic inoculation, occurring through chafing and the use of a dirty napkin.—Dr. Matthews Duncan referred to sloughing cellulitis of the scrotum in males, and analogous cases in the female. He had seen a fatal case of puerperal sloughing of the vulva resembling hospital gangrene with cystitis. Sloughing of the hymen and tags of lacerated tissue was often seen. He had seen a case of linear sagittal sloughing of the perineum after a difficult labour. He had seen both labia gangrenous from the pressure of a large protruded fibroid.—Dr. Hickinbotham had seen two cases; one occurring in a woman lying in a room in which were cases of scarlet fever, the other in a woman whose husband was the subject of erysipelas of the scalp.—Dr. Herman said that in his case the skin seemed to be the seat of dis-

case, rather than the cellular tissue. The puerperal gangrene occurring epidemically seemed to run a more acute course than ordinary hospital gangrene. The sloughing in it affected uninjured tissue, and was quite distinct from the common sloughing of tags of lacerated tissue.

MEDICAL OFFICERS OF HEALTH SOCIETY.

A MEETING of this Society was held at 1 Adam-street, Adelphi, on May 18th, 1883, Dr. T. W. Tripe, President, in the chair.

On account of an outbreak of Small-pox in the Hackney Union Infirmary was given by the President, of which the following is an abstract:—On March 28th the author received notice that a case of small-pox had been removed from the work-house infirmary, and having been consulted as to the course to be taken to prevent the spread of the disease, advised the revaccination of those in the same ward, isolation, and disinfection of the clothes of the sick. Other cases having occurred on April 9th, he recommended more strict isolation and more complete disinfection. The patient had already been isolated from the other inmates, and the medical officer had also begun to revaccinate not only those in the ward where the disease first appeared, but in another ward where cases subsequently occurred. The history of the outbreak is as follows. A man, No. 1, was admitted into the infirmary on March 20th, suffering from secondary syphilis. On March 23rd or 24th a rash appeared, which was at first believed to be syphilitic. On the 27th there was no longer doubt as to the nature of the disease, and he was removed to the Homerton Small-pox Hospital. Before his disease was recognized his clothes were sent away to be washed with others, but afterwards the beds and bedding were taken away to the disinfecting chamber; but probably everything was not removed. On March 26th, No. 2 was admitted into this ward for some slight illness, and was discharged on the 30th. On April 9th, he was removed to the small-pox Hospital. No further extension of the disease from this case took place. On April 8th, No. 3 had the rash of small-pox upon him, having ailed for a day or two previously. On the 9th, Nos. 4 and 5, both in the same ward as No. 1, were removed to the Small-pox Hospital. On the same day No. 6, sleeping in another ward (female), who was engaged in the laundry, was attacked with small-pox and removed to hospital. None of these persons had been revaccinated, but the whole of the inmates of this ward, which was in no way connected with the male ward in which the disease broke out, were revaccinated as quickly as possible. On April 14th and 15th two other cases, Nos. 7 and 8, occupying a third ward, were attacked. No. 7 was employed in the laundry; No. 8 was not, but occupied a bed immediately opposite No. 7. The inmates of this ward were all revaccinated, and everything they had used properly disinfected; and when fifteen days had elapsed from the occurrence of the last case, the ward was emptied. The history of this outbreak is unusually instructive. No. 1 must have received his infection before his admission; No. 2 waited upon him, became frightened on hearing what the disease was, and was removed to the hospital ten after he left the infirmary, and fifteen days after he was exposed to infection, if it be assumed that small-pox is not infectious during the incubation period. At any rate, there can be no doubt as to the source of his infection, nor of Nos. 3, 4, and 5, who were removed to the hospital from the same ward on April 8th and 9th. But the question arises, would these cases have oc-

curred if they had been revaccinated on March 26th as soon as the rash appeared on No. 1. According to Mr. Marson's opinion they would not, as he believes, if revaccination be effectually performed within two, or at the most three, days after exposure to infection small-pox will not result. At any rate, it is certain that no one else suffered as soon as revaccination was performed on all the inmates. The cause of the outbreak in the women's ward is not so simple, as there was no direct communication between the two sides of the infirmary, the only persons passing from one to the other being the medical officers. The facts, however, that No. 6 was employed in the laundry to which infected clothes had been sent without disinfection, and that she sickened about the usual time after the clothes were sent to the laundry, seem satisfactory evidence as to the origin of the disease. No. 7, who had no connection with No. 6, except that both were employed in the laundry, was removed to hospital on April 14th, and No. 8 on April 15th, both of these being inmates of the same ward. How No. 8 caught the disease it is difficult to say, unless the clothes of No. 7 became infected in the laundry; if so, it is not clear why the outbreak in this ward was limited to these two unless the speedy revaccination of the inmates of the ward prevented any further spread of the disease. Considering there were 800 inmates in the infirmary, the rapidity with which the outbreak was stamped out is most satisfactory, especially showing the efficacy of revaccination, for it should be remembered that although three cases occurred in two crowded wards, the disease did not extend further, notwithstanding that judged by the number of successful revaccinations many must have been previously susceptible to small-pox.

Mr. Jacob gave an account of Two Outbreaks of Small-pox in Workhouses which had come under his notice, and in the discussion which followed, Dr. Willoughby, Dr. Dudfield, Dr. Bristowe, Dr. Corner, and Mr. Wynter Blythe took part.

Dr. Willoughby also read a brief paper on the Statistical Reports of the Municipality of Frankfurt-on-the-Main.

ACADEMY OF MEDICINE IN IRELAND.

A MEETING of the Obstetrical Section was held on February 23rd.

Dr. J. S. Poole showed for Dr. Kidd the Uterus, Heart, and Lungs of a Puerpera, who died suddenly on the sixth day. The post-mortem showed a small abscess, at the junction of the right Fallopian tube with uterus, opening into the peritoneal cavity. Here the vermiform appendix and an epiploic appendage was seen adherent. A large clot was seen *in situ*, completely blocking a primary branch of the right pulmonary artery for about an inch and a half. Dr. J. S. Poole also exhibited an Anencephalous Fœtus, the second born of slightly premature twins, the first of which was born healthy and living.

Dr. J. B. Kirkpatrick showed a Uterus and Appendages, with large fibroid tumour in anterior wall.

Dr. William C. Neville, Sectional Secretary, exhibited for Dr. H. Macnaughton Jones—(1) Fœtus and Placenta of six months, in which delivery, complicated by deformed pelvis and transverse presentation, was effected by version, with removal of detrunated head by perforation and craniotomy forceps. (2) A large Fibroid Polypus, which sprang from the cervix uteri, and filled the vagina. There was also a dermoid tumour of bladder from the same patient. (3) A Unilocular

Ovarian Cyst, and a Multilocular Ovarian Cyst, both removed by operation.

Mr. Story showed a patient who had a symmetrically placed Supernumerary Finger growing from each hand. A brother had a similar deformity.

Dr. Atthill read a paper on Metria (so-called puerperal fever). He commenced by saying that our knowledge of the various affections included by the Registrar-General under the term metria, still far from perfect, had of late been steadily increasing. It was now all but universally conceded (1) that there is no such single disease as puerperal fever properly so-called—that is, a specific disease in the same sense as scarlatina or small-pox; (2) that inoculations and absorption of septic matter conveyed from without formed a not infrequent cause of one form of metria—viz., puerperal septicæmia; (3) that puerperæ frequently become self-inoculated by poisonous material generated within their own bodies, either by the decomposition of retained clots or shreds of membranes or placenta, the resulting fever being by some called puerperal sapræmia in contradistinction to septicæmia. He held that the septicæmic form of metria could only be communicated from one puerpera to another by the actual transfer of the pathogenic matter, either by the hands of an attendant, the nozzle of a syringe, sponges, napkins, etc., but not by the medium of the air. To two points he drew special attention, the frequent occurrence of metria in puerperæ who are preyed upon by remorse or mental distress, and the occasional outbreak of a very fatal, infectious, and essentially epidemic form of metria which he believed could not be due to septic absorption. The influence of remorse and mental distress in predisposing to the disease was well seen in the high mortality attending puerperality in women who had been seduced; and if such cases were excluded, he thought that the mortality of the Rotunda Hospital would only amount to one-half its present rate. Here fretting and quickened pulse were the earliest symptoms of danger, a severe form of metria manifesting itself after twenty-four hours. These cases of metria were usually due to self-inoculation, the putrid matter finding a ready inlet because of the deficient post-partum contraction of uterus seen in such patients. Occasional outbreaks of an epidemic and very infectious form of metria were also known to occur, the disease spreading widely among the inmates of a hospital. He could not accept Dr. Evory Kennedy's explanation of these outbreaks, as due to the aggregation of puerperæ, nor could he admit their septic origin, since septic material was not communicable through the air. He held rather that these outbreaks occurring simultaneously with epidemics or other zymotic fevers were really examples of these zymotics, specially modified by the physiological state of puerperal women. The infection of erysipelas could thus induce an attack of infectious metria in a puerperal woman, while conversely such a form of metria could impart erysipelas to her offspring. In the same way scarlatina grafted on a puerpera might result in metria, and not in scarlatina. This infectious form of metria tending to assume an epidemic character was therefore to be considered as consisting of specially modified cases of the prevalent zymotic disease. As strengthening this view, Dr. Atthill noticed the fact that in his experience bronchitis or pneumonia occurring in a puerperal patient was likely to be complicated by abdominal symptoms of the same kind as those which were seen in puerperal septic fever. These views he exemplified by a history of such an epidemic of infectious fever occurring in the Rotunda Hospital in

August last, and which, in the author's opinion, depended for its origin and infectious character upon an imported case of typhus fever in a puerperal patient. The outbreak was completely stamped out by closing and thoroughly disinfecting the hospital for a fortnight. The severe symptoms and rapidly fatal course of this epidemic form of metria differ essentially from the more insidious and less painful progress of puerperal septicæmia, on the characteristics of which he dwelt at length, emphasizing the good prognostic import of a furred, as opposed to a glazed and cracked, tongue during its progress. Diarrhœa, he thought, was in such cases by no means to be considered an unmixed evil. In discussing the treatment of the different forms of metria, he observed that while all but useless in the epidemic form, it was often of great service in the septicæmic cases. He formulated the following conclusions as founded on his experience:—(1) That a disease of a highly infectious nature, differing essentially in its symptoms and course from that the result of septic poisoning, and capable of being propagated in the same manner as other zymotic diseases, occur from time to time among puerperal women; (2) that this disease originates from the introduction into the system of a puerperal woman of the infection of some well-known zymotic disease, such as erysipelas, scarlatina, typhus, and probably typhoid fever, the action of the infection being modified by the peculiar state of the system and of the blood which exists in puerperal women, and that it therefore develops in them an apparently totally different disease; and (3) that the disease thus originating can be easily stamped out by the same means as are known to be efficacious in the case of ordinary zymotic diseases.—Dr. McVeigh stated that he had seen a case in which nervous shock from the sudden news of the Phoenix-park murders had seemed to him to be the exciting cause of puerperal fever.

Dr. Henry Kennedy had formerly seen many cases in the Rotunda Hospital in which the sickness had preceded labour, and he had made post-mortem examinations in many fatal cases. He usually found the inner surface of the uterus in a state of slough, with but slight appearance of peritonitis. The tissues mostly attacked were cellular tissues, which, commencing in the pelvis and spreading up behind the kidneys, were always in a state of complete slough.—Dr. Fraser recommended that hands, instruments, etc., used about a puerpera should be cleansed first in a solution of Condy's fluid, and then in one of oxalic and sulphurous acids.—Dr. Kidd recognized the epidemic and the septicæmic or pyæmic form of the disease. He had long been aware of the former as distinct from the latter. It usually began outside hospitals and spread into them. The last epidemic in the Coombe Hospital had followed only after the disease had been everywhere prevalent around them. At the same time typhus was very prevalent, the Hardwicke Hospital being unable to accommodate it, and other hospitals being proportionately full. The cases of epidemic metria were very rapid, very fatal, and commonly showed symptoms of the disease before or during labour. He had recently been consulted about a lady who had contracted this form of puerperal fever before labour, and who had only survived delivery by little more than twenty-four hours. She exhibited well-marked puerperal symptoms, abdominal pain, tenderness, vomiting, diarrhœa, and fever. Dr. Atthill had succeeded most remarkably in stamping out the outbreak, which he had described, so easily that he (Dr. Kidd) felt some difficulty in thinking that those cases depend on epidemic rather than on local causes. He had always found it very difficult to eradicate a genuine epidemic of metria.

During the last Coombe epidemic that hospital was closed, and thoroughly disinfected, yet on reopening the epidemic again broke out. Again the newly admitted labour patients were transferred to the entirely separate gynaecological hospital which was fitted up for them. There fever also appeared, and deaths occurred; nor did readmission into alternate beds into the freshly disinfected and white-washed labour wards put a stop to the epidemic, which died slowly away of itself. These facts seemed to him to show that it was no hospitalism which sustained the outbreak. This form often occurred concurrently with epidemics of scarlatina and erysipelas; but he could not state the exact relation between them. When a certain epidemic constitution prevailed, all sorts of zymotic diseases flourished. He did not accept Dr. Atthill's view that these different diseases could result from one another; that if they sowed typhus they would reap scarlatina or metria. As in cholera, the first cases of the epidemic were most virulent. The majority of septicæmic cases were, he believed, autogenetic.—Dr. Macan said that of late the belief had been gaining ground that this disease arose simply from septic poisoning. The connection between puerperal fever and such other fevers as scarlatina was not proved, and led only to confusion. On the other hand, it had been clearly shown that there existed a close connection between it and erysipelas, amounting almost to proof, that it was, as Virchow had said, a kind of internal erysipelas. When puerperal fever occurred in a hospital, it was carried in a variety of ways from patient to patient, and thus the epidemic broke out. The difficulty of then getting rid of the septic poison became very great. He disbelieved in the miasmatic theory of its spread, and held that auto-infection was very rare compared to hetero-infection. The puerperal wounds were closed before the lochia or retained membranes were likely to become fetid. Treatment of acute septicæmia was almost hopeless, though he employed antiseptic washing of the uterus. Prophylaxis was chiefly to be regarded. Doubtless the capacity for absorbing septic poisoning was greatly influenced by the nervous condition of the women.—Dr. Neville (secretary) had difficulty in accepting Dr. Atthill's view that prevalent zymotics might give rise to a peculiarly epidemic form of metria. If typhus or scarlatina gave rise to puerperal fever, he saw no reason why lying-in hospitals should ever be healthy, since the students attending them daily attended also the fever wards of general hospitals. The general practitioner also attended all sorts of cases, including midwifery; and, although it might be so, it had not been proved that his midwifery mortality was on that account above the average. Could puerperal fever, itself derived from scarlatina, infect a third person with scarlatina? Such a case would never be recorded. The majority of cases attacked during an outbreak were primiparæ, a fact which could be foretold on the septic theory, but which could not be explained on the modified zymotic one.

Dr. Atthill, in reply, said that Dr. Kidd had observed cases in which women had been attacked by the fever before labour. He thought that in such cases the fever was caused by the infection of scarlatina, typhus, or erysipelas, specially modified by the woman's physiological condition. He did not say that all these diseases had a common virus, but he did believe that they might all cause an epidemic form of metria. This form of the disease he did not think was more frequent in primiparæ than in others. He believed it spread equally through a hospital, as in the example he had given. It was quite distinct from the septicæmic form,

which chiefly attacked primiparæ, and of which 75 per cent. of cases were autogenetic.

Notes on Bloodvessels of New Growths.—Congenital

Defect of the Rectum.—Obstruction of the Inferior Vena Cava.

The Pathological Section met on March 2nd, the President of the Section in the chair.

Mr. P. S. Abraham read notes on the Bloodvessels of New Growths, with especial reference to their origin in granulation tissue. The bloodvessels which are seen in sections of tumours may be considered under two heads—(1) those belonging to the proper tissue of the part into which the neoplasm has infiltrated; and (2) those which have arisen anew and belong to the new growth itself. The former have become enveloped by the new invading tissue, which they afterwards in greater or less part supply. The latter are the vessels of circumscribed growth, and are either prolongations or sproutings from the vessels of the neighboring tissue, or, formed apart, have been subsequently connected with them. The small arteries and veins which come under the first category are often distinctly modified by what appear to be inflammatory changes, and the proliferation of the cells of the coats may go on to such an extent in the case of the intestine that the lumen may become occluded. An extreme case of the vascular wall, thickened and studded with an irregular cell growth, is seen in certain sections of leprosy tumour. The young bloodvessels of neoplasms in general do not always show any distinction of tunica; and sometimes in a quickly growing mass of cells the wall of the vascular channels can scarcely be differentiated from the surrounding cell-tissues. From the consideration of the actions of granulation tissue, which had formed in sponges placed for various periods in wounds and on theoretical grounds, it seems unlikely that Professor Hamilton's new and ingenious mechanical theory of the formation of granulation vessels will be altogether accepted. In the specimens shown the vessels branch freely and inoculate among the fibres of the sponge; they give off-shoots of different sizes, and there is abundant evidence of a new formation of capillaries going on, much in the manner described by Arnold. Even if the capillary blood-pressure were sufficient to produce the mechanical effect of forcing out and elongating the capillary loops, it is difficult to understand how that pressure could cause the cell-multiplication which goes on in the wall of the elongating capillary. The cells of the wall, indeed, are not simply stretched; they increase in number by division and the wall of the capillary grows. Several other arguments were brought forward, and in conclusion it was remarked that, as Professor Hamilton shows, a thrombus in a ligatured artery becomes vascular by the throwing in of granulation loops from the vasa vasorum near the point of ligature—in his own words, "it is nothing more than a granulating surface within a vessel." If this be the case, the pushing in of the loops must be against an intra-arterial pressure certainly greater than that of the blood in the vasa.

Dr. E. H. Bennett read a paper on Congenital Defects of the Rectum, based on the details of a case which he had treated during the winter by laparotomy, failing to reach the bowel by the perineum. The variety of deformity exhibited was that in which the anus and other pelvic organs, except the rectum, were normal, and there existed a cord of variable length connecting the anal cul-

de-sac with the extremity of the intestine. With the specimen recently acquired Dr. Bennett showed three examples of the same deformity contained in the museum of the Royal College of Surgeons, and contrasted these with an example of complete defect of the anus and urino-genital outlet, contained in the museum of the School of Physic, Trinity College. Having directed attention to the views of Giralès and of Curling, who have attributed this deformity to obliteration of the rectum by a pathological process, Dr. Bennett showed from the evidence presented by the specimens that this view was erroneous, and that the lesion is due to the arrest of development of the bowel, the hypoblastic pouch failing to reach the anal inflection from the surface of the embryo. He indicated the probable analogy between the muscular cord connecting these parts and such bodies as the gubernaculum testis. He further demonstrated that attention to the position and relation of the cord might enable the surgeon when operating for relief of the deformity to avail himself of it as a guide to the intestine.—Dr. McSwiney, Mr. Stokes, and Prof. Macalister discussed the foregoing communication.

Dr. F. W. Warren read a paper on the subject of Occlusion of the Inferior Vena Cava, illustrating his remarks with a rare case in which the inferior cava was completely occluded by a calcareous tumour, about the size of a bean, growing by a narrow pedicle from the great Eustachian valve. The tumour completely obstructed the vein at the caval opening of the diaphragm, and was adherent to the lining membrane of the vein. The specimen was taken from the body of a male aged twenty-two years. During life both lower limbs, the front of the abdomen, and the anterior aspect of the thorax, were covered with a close network of varicose veins, the head, neck, and upper extremities being perfectly normal in appearance. The patient stated he had these enlarged veins as long he could remember. He was otherwise perfectly healthy, there being no œdema, no hæmorrhoids, no albuminuria; but he died unexpectedly of enteric fever from perforative peritonitis, and had suffered from œdema of the liver from the onset of the fever. A careful post-mortem examination having been made, the principal channels of the collateral circulation were as follows:—The superficial compensatory circulation was principally carried on by the superficial deep epigastric veins, with the circumflex iliac veins from below anastomosing with the internal mammary and long thoracic veins from above, the course of the blood current being reversed, and passing from below upwards. Within the cava, just as it opened into the right auricle, the tumour already described was discovered. The *venæ cavae hepaticæ* were not obstructed, as a surgical probe could be passed through them into the right auricle. Dr. Warren was of opinion that the tumours commenced as a fibrinous vegetation upon the great Eustachian valve, and then underwent calcareous degeneration, causing very gradual, and finally complete, obstruction of the cava. Upon striking the tumour with a pencil or spatula, its stony and calcareous character was readily demonstrated. The tumour did not in any way partake of the character of the thrombus, as it was round, small, isolated, and attached by a narrow pedicle to the valve. Dr. Warren was also of opinion that the tumour was intra-venous altogether in its origin and development.

Dr. Macalister, commenting on the paper, stated that the total number of cases recorded of obliteration, or absence of the inferior cava, was probably about twenty-three.—Drs. H. Kennedy and Bennett also commented on the paper.

Editorial.

RENAL SURGERY.

THE records of Renal Surgery grow apace, and although Mr. Marshall's remark at the Royal Medical and Chirurgical Society on May 22nd, was very true, that the time has not yet arrived for the formation of definite rules of procedure in this province, the period when such will be possible is not far distant. Those who were present at that meeting enjoyed the advantage of seeing numerous specimens (they might well be called trophies) of surgical courage and skill in this direction. It would have been possible to have amplified the collection, but it well represented the various morbid conditions of the kidney for which surgical relief has of late years been applied, and, on the whole, with such success as to give great hopes for the future. Amongst the specimens were calculi removed by nephrotomy, sacculated kidneys more or less disorganized from impacted calculus, tubercular disease, cystic degeneration, including the enormous renal cyst removed by Sir Spencer Wells in 1878, and malignant growths. The communications made to the Society also embraced a considerable variety of lesions; the most remarkable perhaps being the case of removal of a lacerated kidney by Dr. Rawdon, and many will share the regret that his boldness was not rewarded by success. Mr. Marshall's case came under the same category, although it was not proved to certainty that the suppurating hæmatoma successfully tapped and drained arose from injury to the kidney itself or to its investment, the large amount of urea in the discharge being in favor of the former view. Mr. Thornton's case was one the pathology of which, as Mr. Barwell observed, must remain matter for speculation; it was a remarkable and a unique case. The main questions were those which arise around the cases of Sir Spencer Wells, Mr. Hill, and Mr. Tait, and which are also dealt with by Mr. Thornton in his paper published in our columns. Briefly they may be summed up as follows: 1. What are the indications for nephrotomy in preference to nephrectomy? 2. What is the best mode of performing nephrectomy? 3. Under what limitations should excision of malignant renal tumours be placed? The first of these questions mainly arises with respect to pyonephrosis due to calculous disease—such a case as Mr. Hill's. There can be no parallel between the two operations, *quoad* their severity. Nephrectomy, in the case of a disorganized organ with a thick fibrous investment and tough adhesions to surrounding tissues is a formidable affair, and disasters have not been few. At the same time the successes have been such—e.g., one of Mr. Thornton's cases, and Mr. Tait's case—as to encourage surgeons to adopt this more radical measure. For if the organ be not removed, it is not likely that

it will contract so rapidly as to become quiescent for a long time, although the source of the mischief—the calculus—has been taken away. Such cases of course fall into a different category from those in which a calculus is extracted before it has led to much disorganization of renal tissue—cases of nephro-lithotomy, strictly so-called. In these cases probably the mere removal of the stone is enough. Upon the second point, the great question whether the nephrectomy should be “abdominal” or “lumbar,” there is divided opinion, and cogent reasons for preference of the one over the other measure have been advanced on both sides. All Mr. Thornton’s brilliant cases were “abdominal,” and the advantage to the surgeon of the increased space for his manipulations, as well as facility for exploration of the other kidney, may be considered to balance the greater risk (if it be really greater) of opening the abdominal cavity. But we have here Mr. Tait’s case to show that the abdominal section may occasionally have to be abandoned in favor of the lumbar incision from insuperable difficulties in the removal of the adherent organ. Lastly, as to the propriety of interference in malignant disease, against which Dr. Dickinson urged some strong reasons, it might be well to leave the surgeon to follow the principle applicable to cancer elsewhere—viz., to palliate if he be unable to eradicate. Symptoms may be so urgent, life may be rendered so intolerable by pain, or more directly jeopardized by continued hæmorrhage (as in Sir Spencer Well’s case), that nothing short of marked evidence of generalization of the disease should deter the surgeon from removing the main tumour. Obviously the better plan is so to recognize nephrectomy as a well-justified operation that recourse may be had to it at a stage of the disease when the growth is still limited by the capsule of the organ, and before the patient is exhausted by suffering and loss of blood. Often—and this, alas! is no new fact in the treatment of cancer—the relief will come too late to prevent the secondary dissemination of the disease; but now and again the surgeon may have the satisfaction of prolonging, if not of saving, a life which would most certainly have been sacrificed had his aid not been summoned.

CHEMICAL, PHYSIOLOGICAL AND MEDICO-LEGAL INVESTIGATIONS ON THE PTOMAINES.

THE first part of an interesting memoir on the nature and properties of the ptomaines appears in the last number of the *Archives Italiennes de Biologie*. The term ptomaines is applied to certain substances endowed with highly poisonous properties, resulting from the putrefaction of the brain, blood, albuminoids, and other analogous organic substances. MM. Guareschi and A. Mosso, the authors of the essay in question, have endeavored to separate the several products

of decomposition, and, having obtained them in a state of comparative purity, to determine their physiological action on the body. Before commencing their experiments they thought it expedient to prove the purity of the reagents used—ether, ethylic alcohol, chloroform, and benzine—and their freedom from poisonous alkaloids. They operated on large quantities of these fluids—as much, for example, as fifty litres of alcohol—and satisfied themselves that in ordinary commercial alcohol there is a small quantity of a base which is either pyridine or some closely allied compound. Other investigators have demonstrated the presence of a mixture of substances belonging to the picoline series, and collidine has also been shown to be present. Amylic alcohol, in like manner, often contains pyridine, which may exist in it even in so high a portion as 1 per cent., and which, being itself toxic, may lead to serious error.

The chloroform employed was found to be pure, but the benzine, like the alcohol, had to be freed from the pyridine it naturally contained. In these experiments on putrefying brain the authors experimented with about seventy-four pounds of human brain-substance, which was placed in a large glass receptacle, and put aside for one or two months at a temperature of about 50° F. The contents of the globe, reduced to a magma, had then an extremely unpleasant odor, and were treated with two volumes of purified alcohol acidulated with tartaric acid, in a sand-bath, for several hours, at a temperature of about 140° F. An immense quantity (147 litres) of alcohol was then added, and the whole evaporated to dryness. Fats were removed from the residue by ether, and the remainder was again and again submitted to the action of ether, which was each time evaporated and re-collected. The fluid, now freed from fat, was extracted with alcohol, and this again was exposed to heat, and the volatile products received in hydrochloric acid. There remained in the retort a brown acid liquid, which was once more extracted with ether, and the reactions of this ethereal solution are given at considerable length. The principal substances obtained were ammonia, trimethylamine, and certain alkaloids or ptomaines, the last-named compounds being, however, too small in quantity to enable any analysis of their composition to be made.

The products of decomposing fibrin were next examined chemically, chloroform and tartaric acid being employed as extracting agents, and sufficient of the ptomaine was obtained to permit of an analysis, when it was found to have a composition represented in all probability by the formula $C_{10}H_{11}N$, a base which is isomeric with the *tetrahydromethyl-quinoline* of Jackson—a compound that has properties similar to those of the ptomaine obtained from putrefying fibrin. The results of their experiments on the physiological action of the ptomaine obtained from decomposed human brain may be

summed up in the single statement that in its effects on frogs it resembles that of curara, though incomparably more feeble. Its action was not only feebler than that of curara, but was much more transient. In the case of the ptomaine obtained from putrefying fibrin they ascertained that the chloroform extract of this ptomaine was much more powerful than the chlorhydrate, and in this instance also the general effects produced were comparable to that of curara.

OVERWORK IN RELATION TO EDUCATION.

A GREAT deal has been said and written of late on the subject of "overwork," more particularly in connection with education. It is time that this question received the full elucidation it requires. It is natural that such a term as "overwork" should come into use, and that it should be popularly applied to all forms or classes of injury sustained by the organ of mind in the course of exercise, whether in result of excess or misdirection of activity; but it must be obvious to everyone possessed of even the most rudimentary acquaintance with physiology that the indiscriminate use made of this term is erroneous and misleading, and that the very hypothesis of *overwork* is in itself open to serious question, and what seem to be grave objections.

Let us recall to recollection for a moment what takes place in the case of muscular tissue under ordinary conditions of exercise, when intentionally developed by exercise, and when overstrained by excessive exertion, or, in other words, "overworked." Moderate exercise, as we know, simply consumes the force generated, or, in more technical language, converts potential into kinetic energy. There is just as much material recuperation as will suffice to replace the elements utilized. Pushed a little beyond this, as in "training" judiciously conducted, muscular tissue is first incited to a gradual increase in the amount of work it performs, with the effect of stimulating the recuperative faculty to a little more than merely compensatory energy, so that there is enough feeding to suffice for *growth* as well as *restitution*, and the muscle increases in bulk. This is not, as we know, due to any augmentation in the number of the elements composing the tissue, but to their increased development. They are not more numerous, but they are larger. In point of fact, the fibres attain greater bulk in consequence of the increased stimulation and the larger amount of food assimilated by the tissue, the supply of nutrient fluid, i.e., blood, being augmented quite as much by the local demand for food as by any other condition which may be supposed to determine a special flow of blood to the part. If muscular exercise be increased too rapidly, faster than the rate of growth of the tissue, or if it be increased after the tissue has attained the full limits of a normal growth—which growth, it will be remembered, is

simply compensatory to the work done, as in hypertrophy of the left ventricle of the heart—there will be exhaustion: that is to say, an uncompensated consumption of tissue and, if the work be further increased, exhaustion may proceed so far as to enfeeble the faculty of recuperation, itself, to such an extent that it will no longer even replace normal waste. The stress of the work falls on the nerve-centres, which of course are the sources of energy, but it seems probable that the terminal plates in the muscular tissue, which are probably reservoirs of nerve-force kept charged—as Leyden jars may be charged with electricity—for the purpose of local or reflex activities, may themselves be specially exhausted and rendered incapable of normal action, so that "cramps," stiffness—which is *rigor*, doubtless due to commencing coagulation of the myosin—and local pain or tenderness, often accompanied by fibrillar pains and twitchings, due to local excitations, will ensue. At the same time the nervous system of the muscular apparatus being exhausted, the vasomotor function is impaired, the arterioles of the part affected lose their tone, and the flow of blood through the region is retarded in speed, accumulation takes place, and what may be called atonic or passive hyperæmia occurs, followed, it may be, by the phenomena of incipient inflammation; or if there be not enough of energy for that active state, then passive congestion, transudation, swelling, and oedema will supervene. This is a hasty and very general summary of what takes place, or may occur, in muscular tissue, when it is "overworked." Probably an analogous state of affairs supervenes in the case of nerve-tissue, and notably of the brain, when unduly exercised. There is, however, this essential difference between brain and muscle—namely, that inasmuch as the former is the more delicately organized, and in a sense the most important—albeit it seems likely that nerve-tissue may be developed while muscular cannot be—it is specially protected, so that before "over-work" does serious mischief in the case of nerve-tissue, there are nearly always very distinct indications that the limits of healthy activity have been reached. Under only moderate exercise nerve-tissue does not, as a rule, develop rapidly, nor does it accumulate strength—that is, force held in reserve and available for action. If the brain is to grow—that is to say, grow complex structurally—it must be fed freely, consuming more than sufficient to replace its waste. If it is to feed, it must *work*. There is no way of stimulating the *structural* growth of brain except by intellectual exercise. This is a point of fundamental importance, and it is of cardinal moment in regard to that form of development by training which we call "education." So true, so inexorable, is this law, that not even *general* stimulation by work will suffice. If any special faculty of what we call "mind"—that is, brain function—is to be cultivated, it must be called out by special

training—namely, by work of the special nature it is desired to elicit. For example, there is no reason to suppose the faculty of learning languages can be developed by exercise in mathematics, or the converse. This is a matter not sufficiently well-recognized. A "strong mind" is a well-grown brain, and "bias of mind" is a brain with some one or more of its parts specially developed. Of course heredity has much to do with the question of capability of development, because the young animal is produced "in the likeness" of its parent; but so far as we, as educators, are concerned, our training must be special if we desire to get special results. In the process of brain-growth, or, more accurately speaking, of brain-development, the elements of which the organ is composed are exposed to precisely the same risks and contingencies as the elements of muscular tissue under varying degrees of pressure by work, and, *mutatis mutandis*, the physiological, running into pathological, effects of progressive increase of work are similar to those we have attempted to recall. The faculty of recuperation is in danger of being itself exhausted, and depression of nerve force and atonic congestion supervene. A matter of moment to remember is that although the brain is structurally a packing together of centres, with afferent, efferent, and intercommunicating nerve fibres, it is itself supplied with nerves, and subject to precisely the same conditions of coarse disturbance as other organs. Sometimes we forget this fact, as at others we forget, not so much that it is an organ, as that it is composed of nervous tissue.

The conclusions we deduce from these facts are as follows: "Overwork," properly so called, is not so likely to occur, or if it occur to do mischief, as irregular or disorderly activity. If there be not sufficient time for recuperation in the course of work, exhaustion must take place. If the work done be of such a nature as to put an undue strain on any one faculty, harm may be done, although the brain as a whole may not be severely taxed. If the supply of brain-food be insufficient to enable the recuperative faculty to compensate by food for consumption in use, there must be exhaustion. If work be exacted when any indication of exhaustion is present, it is impossible that injury shall not be inflicted. It follows that educators have especial need of care to avoid engaging the brains of their pupils in work for more than very short periods, and to provide intervals during which there may be rest of the centres specially taxed. Much may be done by changing the kind of work frequently. We are of opinion that no growing child should be kept longer than half or at most three-quarters of an hour at one task, or even the same description of work. Again, the great centres of relation should not be overtaxed. Vision, hearing, the speech centre, and the centre specially concerned with written language, whether in writing or reading, should not be wearied. Brain weariness is the first indication of exhaustion. The

faculty of "attention" is perhaps one of the most easily vulnerable of all the parts or properties of brain-function. It is the faculty which most readily becomes permanently enfeebled, and when weakened entails most trouble in adult life. In children it is difficult to catch and fix the attention. No effort should be spared to secure this fixity of thought; but in order to avoid weakening the power of "thinking"—as distinguished from "thought-drifting"—the teacher should not strive, or desire, to hold the attention by any effort on his part longer than it is voluntarily given by the child. The slightest indication of exhaustion should at once be met by a change of task. If these hints, general as they are, can be reduced to practice, we think there is little fear of "overwork" or harm from brain activity. Desultory and insufficient work is more to be feared by far than "overwork," because the brain, like every other part of the organism, grows as it feeds, and it can only feed as it works.

RENAL CIRCULATION.

THE important connection between the conditions of the renal circulation and the special function of the kidneys lends much interest to the observations made a few years ago by Professor Cohnheim and Dr. Roy, and now published in detail in the current number of Virchow's *Archiv*. The method of research was similar to that which enabled the latter observer to make his remarkable discovery of the independent rhythmical contraction of the spleen, and other facts in regard to the circulation through that organ. It consists essentially in enclosing the organ to be observed within a metal box containing a membranous sac filled with oil, and connecting the apparatus (which Dr. Roy has termed the oncometer) with a recording instrument (the oncograph), whereby the slightest variation in size of the organ can be recorded simultaneously with the kymographic curve of arterial pressure (see *Journal of Physiology*, vol. iii). The instrument allows of such observations being made with least disturbance to the organ, and without interfering with the secretion of urine, and, by registering minute changes, renders the observations more delicate and precise. Under normal conditions the oncographic curve runs parallel with the kymographic; in other words, the systemic blood-pressure and the variations of the volume of the kidney correspond. Changes in the arterial blood-pressure do, however, sometimes influence the quantity of blood in the kidney. If the arterial pressure falls, there is a corresponding fall in the oncographic curve; if it is increased, the volume of the kidney increases. But the reverse is more frequently the case. A sudden sound or movement will cause in the animal a simultaneous rise in blood-pressure, whilst the curve, indicating the volume of the kidney falls; and where the blood-pressure curve is marked by Traube's waves; the curve of the oncograph is

precisely in the opposite direction; the greater the rise in blood-pressure, the more the diminution of the kidney, and *vice versa*. It was also found that there are apparently primary and spontaneous changes in the renal volume independent of changes in the arterial pressure—a slow enlargement followed by a diminution—occurring in both kidneys, but not synchronously nor to the same extent. An explanation of this singular fact is wanting.

In order to fully test this fact of the diminution in the volume of the kidney coinciding with the rise of blood-pressure, the effects of asphyxia, of stimulation of the sensory nerves and of poisoning by strychnine, upon the renal circulation were noted. The temporary suspension of artificial respiration in the curarized animal is followed at once by a rise in the blood-pressure, which is maintained so long as the state of apnoea is allowed to last. Coincidentally with this rise in blood-pressure the volume of the kidney diminishes, the organ returning to its previous size on the return to the normal state of arterial pressure. The rapidity with which this contraction of the renal vessels occurs depends upon the degree to which the blood has previously been oxygenated, the effect occurring the more rapidly the more nearly the blood is dearterialized. The degree to which the renal vessels contract depends also upon the excitability of the vaso-motor system. Thus in one case, where respiration was suspended for 75 seconds, the kidney was reduced in volume 10 per cent.; in another, during a suspension of breathing for 45 seconds, the reduction was 13 per cent.; and in a third observation each kidney was reduced in size 7 per cent. for 30 seconds. Division of the splanchnic nerves had no influence upon this asphyxial contraction, the only effect being that in some cases such division of the nerve caused a slower and feebler diminution in the size of the organ. But when all the nerves supplying the kidney were severed, the kidney enlarged in size corresponding with the rise in systemic arterial pressure. This difference showed that the contraction of the renal vessels during asphyxia was not so much due to the action of dearterialized blood upon the vessel wall as to vaso-motor influences; and it is concluded that the diminution in volume of the kidney during asphyxia depends on two counteracting factors—viz., the elastic tension due to the heightened blood-pressure and the stimulation of the vaso-motor centre, and as the latter preponderates the kidney is reduced in volume from contraction of its vessels. The differences in this respect between various organs must then be referred to the varying degree of excitability of their vaso-motor nerves. Stimulation of sensory nerves produces similar results. When the central end of the divided sciatic was stimulated, the rise in blood-pressure was accompanied by a very marked contraction of the vessels of the kidney, the size

of which was thereby much reduced—a reduction which was maintained for a short time after the stimulation ceased and the blood-pressure had fallen. Here also division of the splanchnics had no influence, whereas after division of the renal nerves the kidney enlarged under the stimulation of the sciatic. Precisely similar was the result of strychnine poisoning so long as the nerve-supply of the kidney was intact.

The generally accepted statement that division of the splanchnic nerves is followed by dilatation of the renal arteries, and consequent increased blood flow through the organ, has not been substantiated by these experiments. Stimulation of the central end of the divided splanchnic at the level of the diaphragm produced a rapid and marked contraction of the renal vessels on both sides, an effect similar to stimulation of the sciatic or other sensory nerves. But an even more marked effect was brought about by stimulation of the peripheral end of the nerve, evidently from the direct irritation of the vaso-motor nerves, the arterial pressure rising at the same time. But the kidney on the opposite side more often than not enlarged in size under such stimulation, and then underwent a secondary contraction whilst the blood-pressure still remained high. At first this was thought to be due to the direct influence of the heightened blood-pressure, when it was found that the degree of secondary contraction was not proportionate to the amount of blood-pressure. It could therefore only be explained by the variable nerve connections between the splanchnic of one side and the kidney of the other.

The difficulty in the complete division of the renal nerves in the hilus, owing to their intimate connection with the walls of the artery and vein, throws doubt upon all deductions from such experiments; but when this can be thoroughly effected, then the renal circulation obeys the same influences as the general circulation, and the volume of the organ increases proportionately with the rise in arterial pressure. The results of stimulation of the renal nerves tend to disprove the existence of vaso-dilator nerves, a fact of some importance, seeing how readily the renal circulation is influenced by agents injected into the blood. But the stimulation of either the peripheral or the central ends of the divided renal nerves, whether only one was selected or several, invariably produced a diminution in the size of the organ—i.e., a contraction of the renal arteries.

Some interesting data were also obtained upon the question of the relation between the two kidneys, as bearing on the fact that when one organ is destroyed the other takes on its function, and becomes hypertrophied. The assumption that this is merely due to a collateral hyperæmia appears to be unfounded, for not only do the kidneys act separately as regards the degree to which they are influenced by changes in the general circulation, etc., but it was found that not the slightest

influence was produced on one kidney when the renal artery of the other was secured by a clamp. No appreciable change in volume was undergone by the unaffected kidney, although the occlusion of the artery was maintained for periods varying from a few minutes to nearly an hour. Such a result is held to support the view already advanced by Cohnheim, that the hypertrophy of one kidney after the removal of its fellow depends, not upon changes in the circulatory mechanism, but upon the altered condition of the blood acting directly on the organ. Nor is any renal hyperæmia produced by shutting off the blood-flow from other branches of the aorta. In one experiment both lower extremities were deprived of their blood-supply by the elastic ligature, without any effect being produced upon the size of the kidney either at the time of application of the ligature or on its removal.

Lastly, the experiments of Professors Cohnheim and Roy tend to show that the generally admitted relation between the skin and the kidney is not so simple as is believed—that it is not a mere question of collateral flux; for in dogs—in which the capability of contraction of the renal vessels had been tested beforehand by the readiness with which they were influenced by stimulation of the sciatic and by intra-venous injection of urea—bathing the surface of the body with cold water for some minutes produced either no change in the size of the kidney at all, or only so slight and temporary a contraction as not to be seriously regarded. The statement, then, that the increased flow of urine during exposure to cold is due to dilatation of the renal arteries, coincidently with the rise in the general blood-pressure, is one which will require rectification; and this point is perhaps one of the most fruitful of the results of a method of research which has already thrown much light upon the mechanism of the circulation in the various organs, and which promises to add still more in the way of refutation or confirmation of various accepted physiological doctrines.

Reviews and Notices of Books.

A System of Surgery, Theoretical and Practical, in Treatises by various Authors. Edited by T. HOLMES, M.A. Cantab., Surgeon to St. George's Hospital; and J. W. HULKE, F.R.S., Surgeon to the Middlesex Hospital, and to the Royal London Ophthalmic Hospital. In Three Vols. Third Edition. London: Longmans, Green & Co. 1883.

THE issue of a new edition of "Holmes's System of Surgery" is an important and welcome event. It has long been recognized as the authoritative exposition of the British school of surgery, and the twelve years which have elapsed since the last edition was published have been so rich in results, both in surgical practice and pathological doc-

trine, that much in that edition has already become antiquated. Important changes are to be observed in this edition. First and foremost among these we must rank the association of Mr. Hulke with Mr. Holmes, in the work of editing. We need hardly say that this is a valuable acquisition to the editorial department, and that no happier choice could have been made; for Mr. Hulke combines in a remarkable degree a large personal experience with wide reading and extended scientific acquirements. Another alteration is the publication of the work in a cheaper form: the five volumes have been condensed into three, not so much by lessening the length of the various essays, or by the exclusion of essays, as by the use of thinner paper, pages of a larger size, and a smaller type. Bibliophiles will regard this change as a retrogression, but as it will place the book within the reach of a larger circle of readers it has our hearty approval. A period of twelve years has unfortunately necessitated many changes in the authorship of the essays. In some cases the writers for the previous edition are no longer among us, while in others they have associated themselves with younger men, who have re-edited their essays; while in a few instances they have stepped aside altogether, and handed over the entire task to others. Speaking generally, we may say that this edition is of considerable value to the student and practitioner. In every part it bears evidence of most painstaking study and revision, and while in some few cases the restraints of joint authorship and joint responsibility may be traceable, on the whole it is a worthy exposition of the beliefs and practice of British surgeons.

The first volume comprises nearly all the essays contained in the first and second volumes of the previous edition. It opens with M. Simon's article on Inflammation, edited by Mr. Holmes; and Dr. Burdon Sanderson's article on the Pathology of Inflammation immediately follows, which has been rewritten and most carefully brought up to date, so that it forms a very valuable introduction to the whole work. Mr. Butlin has rewritten Mr. Holmes Coote's article on Abscess, and the chapter on Tumours and Cancers previously prepared by Sir J. Paget and Mr. C. H. Moore, and he has also edited Sir J. Paget's article on Ulcers. Mr. Butlin has, of course, considerably modified the article on Tumours in accordance with our increased knowledge of the intimate pathology of these growths, and he has introduced several woodcuts of his own microscopical preparations of many of the chief varieties of tumours. Mr. Cripps has edited but not altered Sir J. Paget's article on Sinus and Fistula, and has furnished one on Gangrene in place of that by the late Mr. Holmes Coote. Mr. Holmes has revised the late Mr. De Morgan's article on Erysipelas, and Mr. Clutton has written that on Pyæmia, including Septicæmia, which was previously from the pen of the late Mr. Callender. Mr. Croft has revised his article on Hætic and Traumatic Fever, and the Treatment of cases after Operation, and has also revised Sir J. Paget's articles on Contusions and Wounds. Mr. Hulke has revised Mr. Poland's article on Tetanus. Mr. Warrington Haward has rewritten the article on Delirium Tremens. Mr. Savory's article on Scrofula has been replaced by one by Mr. Treves, and that on Hysteria has been edited by Mr. Holmes; but Mr. Savory is still solely responsible for the chapter on Collapse, which has received only a few verbal alterations for this edition.

In the second part of this volume Mr. Holmes has contributed, as before, the articles on Burns and the General Pathology of Dislocations; Mr. Jacobson has written that on General Pathology of Fractures, and has introduced a description of Fat

Embolism; Surgeon-General Longmore has revised his article on Gunshot Injuries; Mr. Hulke has edited the articles on Injuries of the Head and of the Upper Extremity; Mr. Jacobson has furnished the chapters on Injuries of the Back and Face; that on Injuries of the Neck is still from the pen of Mr. Durham. The article on Injuries of the Chest was edited by the late Mr. R. Lyell, who also edited Mr. T. Smith's article on Minor Surgery, and wrote that on Plastic Surgery. Injuries of the Abdomen and Pelvis are still, as before, described by Mr. Pollock and Mr. Birkett respectively, and Mr. H. Morris has rewritten Mr. Holt-house's article on Injuries of the Lower Extremity. This volume contains four plates and over two hundred woodcuts, the former all illustrating Mr. Treve's article on Scrofula.

The arrangement of the latter parts of the work differs from that of the former edition; thus the second volume contains essays that before were scattered in the third, fourth, and fifth volumes; and Mr. Lee's article on Syphilis, which formerly stood in the first section devoted to General Pathology, is now included, along with his article on Gonorrhœa, in the chapter on Diseases of the Generative Organs—a less scientific but more convenient arrangement. Mr. Hulke has edited Mr. Dixon's article on Ophthalmic Surgery, and has thus been compelled to keep to the lines laid down by Mr. Dixon in the earlier editions. Aural Surgery is described by Mr. Dalby, who has rewritten the article. Mr. A. E. Barker has edited the articles on Affections of the Muscular System and Caries of the Spine, and has rewritten those on Diseases of Joints and of the Tongue. Dr. Brown-Séquard has undertaken the whole subject of the Surgery of the Nervous System; and Dr. Little has revised his articles on Orthopædic Surgery and Scoliosis. Mr. Holmes is still responsible for the essay on Diseases of the Bones, from which we miss any reference to the interesting changes produced in bone by congenital syphilis. Mr. Pollock has again contributed the article on Diseases of the Mouth, Pharynx, Œsophagus, and Intestines. The Surgical Treatment of Stricture of the Œsophagus and the operation of Gastrostomy are, however, more fully discussed by Mr. Durham in the section devoted to Injuries of the Neck. Mr. Warrington Haward has edited and revised the articles on Diphtheria, Croup, and Diseases of the Nose, and Mr. Hensman has dealt in the same manner with Mr. Durham's article on Diseases of the Larynx. Hernia is again treated by Mr. Birkett, and Diseases of the Rectum by Mr. Henry Smith. Dr. Bristowe has revised the article on the General Diseases of the Skin, and Mr. Godlee that on its Local Affections. This completes the contents of the second volume. Scattered through it are two plates and 177 woodcuts.

In the third volume Mr. Holmes has taken the whole subject of the Diseases of Blood and Absorbent Vessels into his own hands either as author or editor, and as he has made this subject peculiarly his own this is a most fitting arrangement. Sir Henry Thompson has written on the whole subject of Diseases of the Urinary Organs, with the exception of a short chapter on Urinary Deposits and Calculi, by Mr. W. F. Donkin. Mr. Hutchinson and Mr. Birkett respectively have revised their articles on the Surgical Diseases of Women and the Diseases of the Breast. Mr. Jacobson has written a very careful article on the Diseases of the Male Generative Organs. Mr. Haward has edited that on Diseases of the Thyroid Gland. Professor Lister has added to his former articles on Anæsthetics, and has revised that on Amputations, and Mr. Holmes has again furnished the article on Excision of Bones and Joints. The arti-

cles in the appendix are by the same authors as before, but Mr. Godlee has edited that on Surgical Diagnosis and Regional Surgery, and Dr. Little has edited that on the Surgical Diseases of Childhood, and has added a chapter on Osteotomy. The article on Hospitals has been excluded, and Surgical Instruments are described in various essays instead of in one specially devoted to them. The third volume contains three plates and over two hundred woodcuts, and it is completed by a very full index which has been carefully prepared.

It will thus be seen that the number of those engaged upon this edition has been reduced from forty-two to thirty-six, and that all the surgeons have been or are connected with nine of the metropolitan hospitals with the single exception of Professor Longmore, of Netley. It is impossible to examine in any way in detail and critically these three large volumes. The essays necessarily vary much in merit, but we are sure that this edition will be highly appreciated by all who will be at pains to study it.

Lectures on Diseases of the Nervous System. By SAMUEL WILKS, M.D., F.R.S. Second Edition. London: J. & A. Churchill. 1883.

THIS work is an excellent fund of clinical knowledge. In many respects it contrasts with other recent works on diseases of the nervous system. Treating as it does chiefly the clinical aspect of disease, it presents a well-marked distinction from those works which deal with the subject from a point of view of pathological anatomy. A fuller description of some forms of disease, and a more copious illustration by means of clinical reports, have increased the size as well as the value of the book. The lectures are written in a conversational tone, which, however pleasant reading for short periods, to some minds rather palls after a long sitting; and there is a laxity of manner, which, if less impressive, is at all events characteristic. A large mind often cannot stoop, or only with impatience, to departmental detail; the skeletal outline and general configuration of a mental conception may be so vividly grasped that the small undulations which disturb the even surface of the great wave are passed over unnoticed. No doubt this state of mind is of great value in almost every sphere of action; it is in the possession of it that the strength and weakness of the author reside. The classification of spinal diseases which has obtained currency during the past few years has been adopted. As the author suggests, these alterations point rather to pathological considerations than to any great advance in clinical knowledge; nevertheless, the clinical side participates in the reflected light of the pathological.

In the preface to this second edition Dr. Wilks says, "There may often be no disagreement about the case which two practitioners are treating, although they may dissent widely about its pathology." We confess that we are unable to coincide with the view here expressed. If there be no disagreement why is there wide dissension about its pathology? Now pathology strikes at the root of all considerations, and if the practitioners "agree to differ" there is an end of the business; but then it must be regarded merely as an instance of good fellowship, which is really an affair of the emotions and not of the intellect. Even if Dr. Wilks means pathological anatomy rather than pathology proper, we fail to see the full force of his remark.

The section of the work on Diseases of the Spinal Cord is greatly improved; the improvement has only been rendered possible by the recent ad-

vances in our knowledge of morbid anatomy and the study of the various reflex actions.

A chapter on Electricity still exists at the end of the book; the chief features of importance from a point of view of diagnosis are given, the characters of the "reaction of degeneration" are just sufficiently explained. So much has been learnt of late years in nerve physiology and pathology that perhaps a complete work, dealing in a precise and accurate manner with all the various questions, could only be expected from the hands of one who has grown up and developed in the midst of this vast treasure of science.

Manual of Gynecology. By D. BERRY HART, M.B., and A. H. BARBOUR, A.M., M.D. Edinburgh: MacLachlan & Stewart.

WE have long held the opinion that the writing of manuals is not the province of the junior members of the profession; the several works of this character relating to gynecology which have appeared during recent years have only confirmed us in our view, and the work before us does not supply grounds for altering that opinion. Although aptitude for teaching is possessed in different degrees by different individuals, yet there is no doubt that special training makes a good teacher just as special training makes a good observer or investigator, and training in teaching is obtained usually only after years of work in observing. The student at the end of his career ought to be, and often is, trained to that point when he may observe and study for himself, but he is far from being an experienced observer, and still farther is he from being an experienced teacher. Long practice in the observation and study of disease, and in the oral communication to students of knowledge so acquired, must elapse before he can become an accomplished teacher. The critical knowledge necessary for the production of a good manual can only be obtained by long experience in a wide field of observation, so that a manual should be the corner stone of a man's work, his last and best. We should welcome with pleasure the appearance of a manual of the diseases of women by one possessed of the qualifications mentioned; it would prove the greatest boon to the student now so commonly taught to refer all manner of symptoms reflexly to the pelvic organs and to interfere locally with those organs in almost every conceivable condition, be it health or disease. The part for which the training of the junior members of the profession has fitted them is not the writing of manuals, but original investigation, and the work before us supplies abundant illustration of this statement. One of the authors, Dr. Hart, is already well known for the excellent work of this kind he has done in the investigation of the anatomy of the pelvic organs and especially of the pelvic floor, work which forms a material contribution to scientific gynecology.

The present book is divided into two parts. The first treats of the anatomy and physiology, and the methods of examination, of the pelvic organs. The anatomical portion is very good, being fuller and better than in any other work of the kind. Much of this is Hart's own work, and he is clearly at home in the subject. In the part devoted to the description of the various methods of investigation too much is made of the volsella and the sound. Their value is really limited, much more limited than the chapters devoted to them would lead us to suppose. The values and uses of different specula are not sufficiently pointed out. It might be not unreasonably inferred from the

chapter on this subject that their chief use was to discover or conceal lacerations of the cervix.

The second part is devoted to the diseases of the pelvic organs. These are divided into affections of the peritoneum and connective tissue, of the Fallopian tubes and ovaries, of the uterus, of the vagina, of the vulva and the pelvic floor. Three more chapters are devoted to disturbances of the menstrual and reproductive functions and the diseases of the bladder and the rectum, while syphilis and chlorosis are considered in an appendix. A great part of this portion of the work is necessarily compilation, and we can scarcely approve the critical judgment displayed by the selections. The account given of both the pathology and symptoms of the various disorders is generally meagre, while much of the treatment recommended is more injurious than the affections for which it is advised. Such, for instance, are stem pessaries for ante flexion and atrophied and small uteri, Sims' and Simpson's cutting operations for ante flexion and so-called pinhole os. On the other hand, the work contains much that is not found in the ordinary text-books, and this is especially true of the chapters treating of the inflammatory affections of the uterus and the vagina. The work is profusely illustrated; it contains nine lithographic plates, and over 400 woodcuts. Were the book regarded simply as an atlas of gynecology we should consider it one of the best published; but we have yet to look for a thoroughly good manual of the diseases of women.

Observations on Lithotomy, Lithotripsy, and the early Detection of Stone in the Bladder; with a Description of a New Method of Tapping the Bladder. By REGINALD HARRISON, F.R.C.S., Surgeon to the Liverpool Royal Infirmary. London: J. & A. Churchill. 1883.

THERE appears to be but little more in Mr. Harrison's remarks on Lithotomy than may be found in most of the surgical text-books of the present day. His own experience of the operation has been very good; for of "over forty" cases in which he has performed it he has met with only two deaths—one, a boy eleven years of age, who died of suppurative pyelitis several weeks after leaving the infirmary; the other, "a gentleman of advanced years," who died of "ammoniaemia." The chapter on Lithotripsy is in the main a description of Bigelow's operation which Mr. Harrison has performed twenty-eight times with two deaths—one from cystitis, and one from extravasation of urine occurring from rupture of the urethra behind an old stricture after the patient had left the hospital. Mr. Harrison recommends this operation for children where the calculus is not over three-eighths of an inch in its longest diameter. The author's contribution to the Early Detection of Stone in the Bladder is the suggestion to use in cases of enlarged prostate sounds of different curves, a long copper probe which can be bent to any shape, or flexible bougies tipped with steel. The concluding chapter in this brochure describes a mode of tapping the bladder through the perineum in cases of hypertrophy of the prostate. A straight trocar and cannula are thrust into the middle line of the perineum three-quarters of an inch in front of the anus, and pushed on into the bladder through the prostate. In the case in which Mr. Harrison has practiced this operation it succeeded very well; for not only was the retention relieved, but atrophy of the gland is stated to have ensued.

Physiological Cruelty; or, Fact v. Fancy! An Inquiry into the Vivisection Question. By PHILANTHROPOS. pp. 156. Tinsley Bros. 1883.—This work gives, in a small compass, the principal facts and most obvious reasonings on the question of experiment upon living animals, and is intended for professional men who have not time to consult works of reference, and for non-professional readers who are anxious to fully understand the position, both moral and utilitarian, of the physiologists. It is extremely clear and logical in its argument, and the data on which its reasonings and statements are based are fully set out in an appendix which forms nearly one-third of the volume. We can recommend its perusal by both lay and professional readers, as dealing thoroughly with the moral principles by which vivisection is justified, and as giving accurate and trustworthy accounts of the relations of experimental physiology to medicine in the past, and the extent of the practice in England at the present time. The recent discussion at Oxford on the vote for a physiological laboratory has again brought up the subject in the public press, and so its appearance is all the more opportune. In the earlier chapters we are led step by step to the conclusions of the author on pain, cruelty, and our rights over animals; and the clearness and want of prejudice which are shown in their discussion are very striking in comparison with the hasty judgments and rash assertions which are generally employed when these subjects are referred to. The limitations by which experimenters are morally bound are most clearly and explicitly stated. The next chapters are devoted to the nature and extent of vivisectional experiments in England, to their relations to physiology and to medicine, and the illustrations are largely drawn from Professor Gerald Yeo's lectures published in our columns last year. Professor Robert McDonnell's address to the Surgical Society of Ireland in 1878, and Professor Heidenhain's well-known pamphlet, "Die Vivisection in Dienst der Heilkunde," The appendix contains an enormous number of quotations from different writers, proving not only the utility but the absolute necessity of making experiments on the lower animals. A list of the scientific witnesses examined by the Royal Commission divides them into those who considered experiments necessary for original research, and those who were of an opposite opinion. These were two out of forty-seven, and the list should be consulted by those who believe that "doctors disagree" on this question. The most valuable portion of the book in some respects, and the most important to those who have been influenced by the agitation and reiterated assertions of the antivivisectionist press on the uselessness of experiment, is that part of the appendix in which the recent work of another objector—Mr. Lawson Tait—is criticised and answered. Another chapter in the book deals with the legislative restrictions on vivisection, and shows how oppressively some of these have worked; but as Sir Wm. Harcourt has recently stated in the House of Commons that it was now his practice only to allow certificates upon the recommendation of the Association for the Advancement of Medicine by Research, we need not refer any further to this part of the subject. In conclusion, we must again express our opinion that this is by far the most important contribution to the vivisection controversy that has come under our notice, and, in the words of the author, we commend it to the "dispassionate consideration of all who can place truth above feeling—still more, above prejudice."

Archives de Neurologie, Vol. V., No. 15. Paris. 1883.—Altogether the current number of this

quarterly journal is one of average excellence. A contribution to the study of the localization of cerebral disease by Dr. Ballet forms the opening paper; four cases are described, in each of which a crural monoplegia was associated with a lesion situated about the paracentral lobule of the opposite side of the brain. The next two papers we have already had occasion to notice, one by MM. Pitres and Vaillard on non-traumatic peripheral neuritis, the other on neuro-muscular hyperexcitability by Charcot and Richer. A long clinical description of a case of otorrhoea, associated with signs pointing to a coarse lesion of the brain, possibly the result of meningitis, is given; the morbid signs indicative of cerebral disease suddenly disappeared whilst the patient was *en route* for Lourdes. A critical anatomical study of the plexuses of spinal nerves by Féré is an elaborate paper on interesting and disputed points. The next chapters are devoted to the production of abstracts selected from various papers on neuro-pathology and the pathology of mind. The remainder of the number is taken up with reports of learned societies, reviews of books, and items of medical news.

Elements of Histology. By E. KLEIN, M.D., F.R.S. Illustrated with 181 Engravings. London, Paris, and New York: Cassell & Company. 1883. pp. 352.—This is the first of a new series of manuals, by men of good repute, intended for students about to present themselves for the preliminary and pass examinations at the College of Surgeons, and the corresponding examinations of other examining bodies. If the other volumes that are promised—on Human Physiology by Mr. Henry Power, on Pathological Chemistry by Dr. Charles H. Ralfe, on Surgical Pathology by Dr. A. J. Pepper, and on Surgical Applied Anatomy by Mr. Frederick Treves—are at all equal to the volume before us, we venture to predict a very great success for this the first venture of Messrs. Cassells in the domain of medicine. It is simply excellent: short, clear, intelligible, well illustrated, written by an acknowledged master, it leaves nothing to be desired, and is yet so small that it can be slipped into the pocket. The only addition we should be inclined to suggest to increase its usefulness would be a short chapter on the methods of investigation in histology.

Anatomy; Descriptive and Surgical. By HENRY GRAY, F.R.S. Edited by T. Pickering Pick, Surgeon to St. George's Hospital; Examiner in Anatomy, Royal College of Surgeons, England. Tenth Edition. London: Longmans. 1883.—The appearance of a new edition of so well known and valuable a work as "Gray's Anatomy" hardly requires notice, but this edition is of more than usual importance, as the editorship has now passed from the hands of Mr. Holmes into those of Mr. Pick, who has most ably discharged the duty. Whilst the general character of the work is carefully preserved, some parts in the sections on Microscopical Anatomy have been rewritten, and a few corrections made in the descriptive portion of the book. Many new illustrations, diagrammatic but very clear, have also been introduced, and this edition in every respect fully maintains the reputation secured by its predecessors of being the most popular text-book on anatomy in our language.

Clinical Lectures on Diseases of the Urinary Organs. Delivered at University College Hospital by Sir HENRY THOMPSON, Consulting Surgeon to University College Hospital, etc. Seventh Edition. London: J. & A. Churchill. 1883.—We are glad to find that within the short period of a year Sir Henry Thompson has been called upon to publish

a second issue of the student's edition of his well-known Clinical Lectures. It is the best evidence of the appreciation it has met with. This, the seventh, edition contains two additional lectures on the subjects, on which Sir Henry Thompson has of late been addressing the profession: the digital exploration of the bladder from the perineum through a small incision into the membranous urethra, and the possibility and advantage of removing tumours of the bladder by forceps passed into the bladder through the same wound.

What to do in Cases of Poisoning. By WILLIAM MURRELL, M.D. Third Edition. London: H. K. Lewis.—This edition of Dr. Murrell's book is, practically speaking, a new work; the text has been entirely rewritten, and the most valuable addition has been made by the statement of the symptoms of the various poisons, an omission which, to a certain extent, marred the usefulness of the former editions. It contains plain straightforward directions for the treatment of the common poisons, and will be invaluable to practitioners in those cases of sudden emergency which may arise in any moment and at any place in these days of what may be almost called free trade in poisons.

Tapeworms: their Sources, Varieties, and Treatment. By T. SPENCER COBBOLD, M.D., F.R.S. Fourth Edition. London: Longmans, Green & Co. 1883.—The fact that a fourth edition of Dr. Cobbold's work has been called for is unmistakable evidence of its usefulness as a practical guide to the profession in the treatment of tapeworm. Eighty additional cases from private practice have been added to the hundred contained in previous editions, and it may be safely recommended as the most useful and convenient book on the subject of which it treats in the English language.

Medical Annotations.

"Ne quid nimis."

TREATMENT OF PUERPERAL CONVULSIONS BY HOT BATHS.

In a paper by Dr. Carl Breus, in the *Archiv für Gynäkologie*, is given an account of eleven cases of puerperal convulsions treated by diaphoresis produced by means of hot baths. Other means, as the inhalation of chloroform, and the administration of chloral hydrate, were also employed. The convulsions set in at different periods during labour, and in the course of the first day after delivery. In four cases they came on at the beginning of labour, in two after the first stage had lasted some time, in one during the second stage, and in four a few hours after delivery. One only of the eleven cases died. There was present in all the cases albuminuria, together with more or less oedema. The baths were employed after the convulsions set in, during and after labour. A case is also mentioned in which forty-five hot baths were given during pregnancy. The author believes that the immediate danger to life in these cases is due to the diseased state of the blood—hydræmia—shown by the albumen and anasarca; and that the rational treatment of this condition consists in the production of a rapid change in the blood-state. This he believes is brought about by profuse sweating, which, he states, diminishes the quantity of albumen in the urine, and the oedema. The hot baths have occasioned no bad symptoms in the author's practice; they have not

brought on premature labour when used during pregnancy, nor have they occasioned hæmorrhage when employed soon after labour.

DIGITAL DILATATION OF CONTRACTED PYLORUS.

ANOTHER method has been added to the short list of the resources of the surgery of the stomach, the treatment of the organic diseases of which organ have until comparatively recent years been left entirely in the hands of the physician. Professor Loreta, of Bologna, proposed that forcible dilatation of the pyloric orifice in cases of simple stricture might be substituted for the operation of resection of the pylorus. In the *Journal de Médecine* a record is given of two cases which, so far, have been completely successful; both patients were operated on by Loreta. Briefly, a longitudinal incision was made through the abdominal parietes to the right of the linea alba; the stomach was reached, drawn forwards and incised near the pylorus; so as to enable the right index-finger of the surgeon to be inserted into that orifice, which was by this means forcibly dilated. It would be of much interest to know what the final issue of such cases would be. Looking to the nature of the cicatricial tissue, would it not be right to think that relief could only be of comparatively short duration?

THE ANTIQUITY OF MAN.

An interesting discovery, of much importance for geological and archæological science, has recently been made in a coal-mine at Bully-Grenay, in the French department of Pas-de-Calais. A new gallery was being pierced, when a cavern was broken into, which discovered the fossil remains of five human beings in a fair state of preservation—a man, two women, and two children composed the group. The man measured about seven feet, the women six feet six and six feet, the children four feet and rather less than this. In addition, some fragments of arms and utensils of petrified wood and of stone, with numerous remains of mammals and fish, were brought to light. A second subterranean chamber enclosed the remains of eleven human bodies of large size, several animals, and a large number of various objects, with some precious stones. The walls of the cave exhibited drawings representing men fighting with gigantic animals. Owing to the presence of carbonic anhydride a third and larger chamber, which appeared to be empty, was not searched. Five of the petrified human remains will be exhibited at the mayoralty of Lens. The remainder of the bodies which have been brought to the surface are to be conveyed to Lille, there to await a thorough examination by the experts of the Faculté des Sciences. Information has been telegraphed to the representatives of the Académie des Sciences of Paris and to those of the British Museum. If the discovery be a real one, no doubt can be entertained of the value of the find, which would on the face of it seem to show that prehistoric man is anything but a myth.

THE TUBERCLE BACILLUS.

In the present state of the pathology of tubercle, perhaps the most needed and useful contributions are the records of numerous facts which, however dissimilar, may be fearlessly allowed to intermingle, with the firm belief that some day all the items will be explained, and all the facts arranged in their appropriate order. M. Malassez has been unable to detect the characteristic bacilli in a tuberculous nodule removed from the forearm of a child dead of tubercular men-

ingitis; but he has met with spherical or oval cellular masses, which he names "zoocléiques," and which, when injected into several guinea-pigs, was followed by the appearance of tuberculosis in these animals. The cellular masses are apparently of the size of some micrococci, and Malassez asks whether they may not be an embryonic stage of the bacilli of Koch. No difficulty would be found, according to Malassez, in distinguishing between the monas tuberculosum of Klebs and the micrococcus in question. In conclusion, it was stated that the guinea-pigs experimented upon were placed under the best possible hygienic conditions, and only a minute quantity of tuberculous material was injected; the masses "zoocléiques" were discovered in the morbid products of the guinea-pigs.

DEATH FROM THE STING OF A BEE.

FROM time to time we are startled by the news of a death following so closely on the sting of a bee that no reasonable doubt can be entertained of the causal relationship. The occurrence undoubtedly belongs to the chapter of accidents; and an explanation can only be obtained by considering those kinds of things which are of an exceptional nature. A sting of an ordinary bee on an ordinary man is perhaps never followed by anything more than a local reaction. To explain the lethal effect, therefore, we must suppose that the virus of the bee was of an unusual nature, either as a result of admixture from without or as a consequence of some disordered action of the physiological processes of the bee. If the fault do not lie in the insect, then we must turn to the other factors of the resultant effect. There can be no doubt that the injection of the venom directly into a vein is a very dangerous matter; and it is possible that this may be the accidental circumstance so necessary to afford a reasonable explanation. We learn from the *Sheffield and Rotherham Independent* that a small farmer, aged fifty-nine, whilst in good health and working in his garden, was stung in the eyelid by a bee; the signs of collapse rapidly set in, and the unfortunate man died within half an hour of the receipt of the sting. It is worthy of remark that the daughter stated that her father had been twice previously bitten by a bee and was very ill on each occasion.

THE PROGRESS OF CHOLERA.

SINCE the beginning of the fourth week in June, when cholera was first announced to be prevalent at Damietta, the disease rapidly acquired epidemic proportions both in that town, at Mansourah, and at Samanoud, besides appearing either continuously but to a less extent in other towns, such as Cherbine, or, again, in isolated groups or in single sporadic attacks at other places. Damietta has hitherto borne the brunt of the epidemic, and some 15,000 deaths have occurred from cholera in that one town. Nearly 400 deaths have taken place in Mansourah, where the disease is now on the increase, whereas at Damietta some considerable diminution in the daily number of fatal cases has at last occurred. So far the disease has been entirely limited to the Delta of the Nile, and, with the exception of an outbreak at Menzaleh, it has confined itself to towns situated along the lines of railway; in other words, its operations have been almost exclusively manifested along the main channels of human intercourse. Quarantine measures have been adopted in most European countries; but our Government have wisely decided to trust to the system of dealing with the sick and with infected things, and to leave the healthy at

liberty. The effects of quarantine, as rigidly carried out, are already manifest in all their cruelty at Mansourah, where the suspension of all intercourse with the outside world prevents any food supplies from being taken in, and so this town, with its population of 16,000 souls, is hemmed in by bayonets to contract cholera or die of starvation. But whilst discarding this barbarous and antiquated system, our Government has decided to take all such precautions as are necessary for the protection of this country. The present order relating to the importation of cholera and similar foreign diseases is to be strengthened and re-issued. A Departmental Committee is to be appointed to sit in London under the orders of the President of the Local Government Board, and a physician connected with the India Office is to proceed to Egypt with a view of maintaining efficient relations with the home Government. Our Port Sanitary Authorities have had full warning as to their responsibilities. The distance between Egypt and our shores will go far to prevent any unexpected occurrences of cholera in ships not already obviously infected at the time of their arrival, and we may fairly hope that even if cholera should be imported the arrangements which are now, or will shortly be, in operation in our several port districts will amply suffice for such work of isolation and disinfection as will be necessary to prevent further extension of the disease.

TYPHUS AT LIVERPOOL.

As yet typhus has shown no signs of diminution in Liverpool. According to the weekly returns of the Registrar-General, no distinction is drawn between the various forms of continued fever, but the fever deaths, which in the five weeks ending May 26th numbered 49, amount again to 42 for the same number of weeks ending June 30th, and, according to a statement made at the last meeting of the Toxteth-park guardians, the disease was spreading to districts hitherto free from infection. Some sort of arrangement has been entered into between the guardians and the corporation with regard to the isolation of the sick—an arrangement which will apparently involve the pauperization of all who are compelled to accept it. This result is the more unfortunate because it is alleged that "in most cases" the fever does not exist amongst persons in receipt of relief. We trust, however, that the scheme is merely a provisional one, and that in view of the fact that Liverpool now contains numerous centres of typhus infection, which will probably constitute a far greater source of danger to the population as winter advances than they do now, the corporation will, in their capacity as a sanitary authority, lose no time in securing the protection of public health by the provision of such means of isolation as will not involve the disgrace and disabilities which attach to the use of an establishment under Poor-law authority.

RISKS OF PRACTICE.

MEDICAL MEN are always liable to have their actions misconstrued, but it has been reserved for these latter days to see a father suing two doctors because they trusted to the parental instinct too implicitly. For only a short time since a jury was engaged in the Queen's Bench Division upon a case in which this state of affairs was literally true, and yet the jury could come to no agreement. The plaintiff in the action was a manufacturing chemist, and his son took ill with diphtheria, for which tracheotomy was performed by one of the two medical men in charge, and against whom this action has been raised. The operation necessi-

tated the immediate freeing of the trachea from materials occluding it, and the father was directed to suck the tube, which he did twice. The onset of the disease had been so sudden that it was legitimate for the surgeon to think the case one of inflammatory croup and not diphtheria. Two or three days after the operation the child died, and the father fell ill from diphtheria. His accusation was that he had not been warned that the disease was diphtheria, and he had not been directed to use any antiseptic gargles after sucking the tube. But it was clearly proved that there was no absolute indication of diphtheria in the child's throat until the day after the operation; and, even if there had been, what could have been more natural than that a father should have lent his aid in saving the life of his child? Moreover, it could not be actually proved that the parent had been so inoculated, since he was living under the same conditions as the child who was attacked first with the disease. Two things are clear—the doctors were quite justified in appealing to the father to come to the aid of his child; and, secondly, they were not at the time in a position to judge of the infective character of the disease so as to warn the parent of a possible risk to himself in doing what was in truth his duty.

CRUELTY TO ANIMALS.

THE Royal Society for the Prevention of Cruelty to Animals is doing excellent work, and when we contrast the state of matters in the streets now with that which even middle-aged men must remember in relation to the treatment of the dumb part of the creation, it is impossible not to feel thankful for the improvement which has been effected. One excellent feature of the work done by the Royal Society has hitherto been its freedom from "fads." The enterprise has been catholic, and it has not lent itself to private or clique influences. The medical profession will not yield place to any other profession or class of the community in its abhorrence of cruelty. It may, indeed, claim to have done more than many, if not most, other sections for the amelioration of the condition of the brute world. Those who characterize medical men as devoid of humanity, or addicted to cruel practices, because they have recourse to vivisection for scientific purposes, are either ignorant of, or wilfully distort, the facts. We heartily wish the Society success, and offer our congratulations on the highly successful meeting at which Her Royal Highness the Duchess of Connaught recently presided.

WHOOING-COUGH IN SCHOOLS.

It is a sign of the increased attention paid to sanitary and hygienic matters generally that the managers of our educational institutions are awakening to a sense of their responsibility as to the means best adapted to guard against the introduction and spread of epidemic disease in their establishments. Until quite recently there was a kind of fatuous belief that epidemics must occur from time to time as a matter of course, and be patiently endured. But nothing is more erroneous or opposed to the teaching of sanitary science. To obviate the occurrence of an outbreak, what is needed is vigilance to prevent its entrance and prompt recognition of the disease when by accident it has made its appearance, so that it may at once be completely and efficiently isolated—in fact, the establishment of effective and systematic medical supervision. The methods by which complete isolation can be secured are by no means a matter of difficulty with schools, especially those

that have no day boarders. On the occurrence of an epidemic in a town all communication with the townspeople should cease, the boys be confined to the school-grounds, the washing be done on the school premises, and by persons whose families are known to be free from the disease. A watchful eye must be kept on the health of the inmates of the baker's shop and also of the school dairy. Instead of going on Sundays to the parish church, services ought to be held in the school-room. If a boy complain of even the slightest malaise he should be at once separated from his companions till seen by the doctor, and in case the disease prove of an infectious nature he should be promptly removed to the sanatorium. In schools where arrangements of this kind are complete, serious outbreaks are rare. At Marlborough, where some years ago outbreaks of scarlet fever were of frequent occurrence, since the inauguration of a system of medical supervision the disease has been kept in almost total abeyance. At Winchester, where the means of isolation are very complete, our Commissioner on the Public Schools, 1875, reported that "in the last ten years there have been only two deaths from zymotic disease in the whole school, and no outbreak of scarlet fever has occurred now for some years." What has been effected at these large schools can be as readily carried out in smaller establishments. The frequent breaking up of schools on account of epidemics is a reproach on their management, and is an evidence that the proprietors do not avail themselves of the means sanitary science has placed at their disposal for dealing with these diseases at the very outset. With regard to the spread of whooping-cough, about which our opinion has now been asked, we can only say that the very best results are to be obtained by rigorous exclusion of the boys from the town and the frequent inspection of them by the school doctor, in order to detect the first symptoms of disease and thus secure early isolation. These precautions should be continued so long as the disease is prevalent in the neighborhood. We are pleased to see that the Council of the Parkes Museum have recognized the importance of the subject of school hygiene by devoting a lecture to its special consideration, an abstract of which will appear in our columns. Among the many subjects touched upon by the lecturer none is of more importance than the considerations for preventing the occurrence of epidemics in our educational establishments, and it is one that for years we have specially insisted on.

ACTION OF DRUGS ON SECRETION OF MILK.

We are already acquainted with the fact that a certain number of medicines when ingested by the ordinary channel were, in part, eliminated by the secretion of milk, but we do not possess precise information concerning the influence of the medicaments on the quantity and quality of the secretion. Observations recently made by M. Strumpf on the milk of goats as well as on the secretion in the human female during lactation have in a measure supplied this want. Iodide of potassium was found to lead to a marked fall in the quantity of the fluid secreted, the proportion of proteid and saccharine principles was increased, whilst the proportion of fat was diminished. The quantity of iodide secreted was very small, so that the notion that iodide of potassium can be administered to children by way of their nurse is not sustained. Alcohol increased the richness of milk in fats, whilst the proportion of albuminoids and carbohydrates was not modified. Unaltered alcohol was not detected in the milk. Neither alcohol, morphia, nor the preparations of lead had

any influence on the quantity of the secretion. Salicylic acid seemed to excite secretion a little; pilocarpine exercised no effect in this direction. The richness of the milk in sugar was increased by salicylic acid, which passes out of the milk secretion in greater quantities in the human female than in the herbivora. Traces of lead were also recognizable in the milk of those subjects who were ingesting the preparations of lead.

THE CHOLERA IN EGYPT.

THE diminution in the cholera mortality at Damietta and Mansourah which has been in progress for some time past appeared in itself a hopeful feature of the epidemic, but it was unfortunately accompanied with a large increase in the number of infected localities, the disease gradually making its appearance day by day in towns, lying for the most part along the line of railway towards the Egyptian capital, which had heretofore remained free from infection; and lastly, the spread of the infection to Cairo itself, a spread which had been so much feared, but which it was still hoped might be averted, became an accomplished fact. At the same time a steady mortality has been maintained at Samanoud, Menzaleh, and Cherbine, and isolated attacks have occurred at Alexandria. The latter are, however, of a doubtful character and, if it be not too late, a great effort will be made to keep that port free from infection. As regards Cairo and the greater part of Egypt, we fear that little can now be done to avert the progress of the epidemic. The measures of sanitary improvement which are needed are far too sweeping in their character to admit of their being carried out on a sudden emergency, such as the present one affords. Even Damietta, where the disease first appeared, remains much in the same sanitary state as it did when cholera broke out there in the middle of June, and probably nothing short of a general conflagration would suffice to remove from the midst of the principal towns now affected those conditions which must necessarily tend to favor the spread of a disease which finds in filth the principal elements for its propagation. But strong measures are needed to save both our troops and Europe from infection, and it is to be hoped that our Government will not allow itself to be fettered by the Egyptian Government, or by any Commission under Egyptian control, in effecting these important and imperial objects. We found it necessary to step in and take supreme control in face of the military danger to which Egypt was exposed last year, and the utter incapacity which has been hitherto displayed in face of the present danger from cholera calls for resort to similar measures at the present stage. In short, the Egyptian Sanitary Board has tried its hand, and failed. We cannot submit to its dictates in so far as our troops are concerned, and the only alternative seems to be the immediate appointment of a Sanitary Commission, composed of British officers and medical practitioners, many of whom are on the spot, and who have had wide experience of cholera in India and our colonies. Not a few, we fancy, have given but a half-hearted assent to our condemnation of quarantine as a measure of cholera prevention; but the experience of the present outbreak in Egypt has fully confirmed the views we expressed, and has shown that this measure, even when carried out with a stringency which has involved acts of gross inhumanity, fails to stay the spread of disease. No quarantine measures can be so rigid as to escape evasion. Cholera in Egypt has, notwithstanding all sanitary cordons, steadily progressed along the lines of human traffic; and should it unfortun-

ately extend to Europe, we shall feel more trust in an efficient system which involves the careful examination of all suspected vessels and persons, together with the adoption of measures for dealing with infected persons and things, than in a system which herds the healthy and the sick together under circumstances which offer every inducement to fraud and evasion.

BATHING AND CRAMPS.

A SAD instance of fatal cramp from bathing occurred at Durham a short time since. A fine young fellow, a trooper in the 3rd Dragoon Guards, then on the March from Edinburgh to Manchester, took advantage of the night's halt to have a dip in the Wear near that city. Being strong and a good swimmer, he took an oar, at which he worked for some time in the sultry evening till he came to deep water, and in a suitable place took his plunge. That he was immediately seized with cramp is evident from the statements of his companions, who, alarmed at his cries, hastened to render assistance, but he had sunk before they reached him, and he never rose again. When the body was recovered, a considerable time afterwards, it bore every evidence of the cause of the disaster. It was described as being "twisted"—that is, contorted; while the vessels of the head, especially in their gorged condition, pointed to congestion, in fact to stagnation of the circulation! That this young soldier lost his life by bathing when in an overheated condition is quite clear. It would be well if soldiers and civilians would remember the lesson conveyed in the classical case of Alexander, quoted by Dr. Jones from "Quintus Curtius"—viz., "It was in the middle of one of the hottest days of a burning summer that Alexander arrived on the banks of the Cydnus. The freshness and clearness of the water invited the King, covered with sweat and dust, to take a bath. He stripped himself of his clothes, and, his body all in a sweat, he descended into the river. Hardly had he entered when his limbs became suddenly stiff, the body pale, and vital heat seemed by degrees to abandon him. His officers received him almost expiring in their arms, and carried him senseless to his tent." The account goes on to show the means taken for his recovery; but it is evident that his life was in great jeopardy from cramp, and that he was just saved by the speedy action of his attendants.

PROFESSOR HUXLEY.

THE election of Professor Huxley as President of the Royal Society will meet with general approval. No ordinary man can aspire to fill the place which has been occupied by so many brilliant predecessors, and much is expected of him who is the chosen representative of English science. The requirements of the office are numerous: he who holds it must be thoroughly versed in at least one branch of human knowledge, and be regarded by those who are most familiar with it as its most brilliant exponent. But he must be something more than this, and be capable of recognizing and appreciating the value of other lines of thought and research than those at which he has worked. Lastly, he must be fitted to conduct the business relations of a large and rich society. No one combines these qualifications for the office more perfectly than Professor Huxley. He has been an energetic and steady worker, and is the unrivalled head of biological science in this country. He may be ranked next to Darwin himself as the ablest exponent of the doctrines of evolution, which have had so powerful an influence on every department of knowledge. He is a subtle

dialectician, and as a man of wide and liberal education may be depended on to promote the cause of science by every legitimate means.

FLOATING HOSPITALS.

THE German Admiralty, it is reported, are going to try a novel experiment, as they intend to send a complete hospital ship to accompany the Baltic squadron on its evolutionary cruise. A corvette has been fitted with cots, requisites for the sick and wounded, instruments, and operating tables. It is intended that in any future war the vessel shall accompany the fleet into action, carrying the Geneva flag, and, in order to distinguish her, she has been painted white with a red streak.

Correspondence.

"Audi alteram partem."

"EXCESSIVE SWEATING OF THE HANDS."

To the Editor of THE LANCET.

SIR—Your correspondent, "Puzzled," would find the following treatment for the above both efficacious and satisfactory.

The patient should soak her hands night and morning in warm water, in which should be dissolved about two drachms or half an ounce of the chloride of ammonium, and about twice as much carbonate of soda (crystals), enough water to be used to well cover the hands. I generally prescribe for my patients sufficient for six applications, and, as skins vary in tenderness, tell them to use as much as will temporarily to a slight extent cause the wrinkling known as *cutis anserina*, a condition which I describe to them as looking like the hands of a washerwoman. After well bathing, the hands are to be well rubbed with the following embrocation:—Tincture of iodine one drachm, compound camphor liniment and glycerine of each a drachm and a half, and compound liniment of belladonna one ounce. (If for the hands, a drachm of *eau de Cologne* makes the embrocation more agreeable.) The embrocation to be applied twice a day. A cure quickly follows. This treatment is equally appropriate and successful for excessive sweating and even bad smelling feet, for that odor is due to the excessive function of the sudoriparous glands.

I am, Sir, your obedient servant.

FREDK. H. ALDERSON, M.D.

Seutherton House, Glenthorne-road, Hammersmith, July 21st.

To the Editor of THE LANCET.

SIR—All the cases of "hyperidrosis" of the hands that have come under my notice I have found to be due to some one of the protean forms in which dyspepsia is wont to manifest itself. The first thing to do, then, is to regulate the digestive system. In the case of a young girl aged seventeen who consulted me lately for this complaint, I pursued the following line of treatment with marked success:—Every day, one hour before dinner, I gave five grains of compound rhubarb pill. Immediately after the three principal meals of the day I ordered a teaspoonful of Fellows' compound syrup of the hypophosphites in a wineglassful of cold water, with once or twice a week an aloes and myrrh pill. From her dietary I excluded pastry in any form, and recommended fish, fowl, and tripe whenever the last-mentioned article could be procured, giving directions that it should be thor-

oughly well stewed; also plenty of skimmed milk, but no tea or stimulant (alcoholic) of any kind. Night and morning the hands were to be well sponged with belladonna liniment, and whenever she washed her hands I directed her to pour a teaspoonful of Jeyes' purifier into the water used. This local treatment I have also found most beneficial in hyperidrosis of the feet with offensive smell.

I am, Sir, yours, etc.

W. A. GORDON LAING, M.B.

Tregony House, Mevagissey, Cornwall, July 23rd, 1883.

SANTAS OIL IN PSORIASIS.

To the Editor of THE LANCET.

SIR—In the face of so many different remedies, both external and internal, for the above complaint, I should hesitate to draw the attention of the profession to the value of another application were it not for the fact that most of the medicaments used for this complaint are the reverse of cleanly.

In a case of psoriasis of fifteen years' standing, where nearly every kind of treatment has been tried—including long courses of arsenic (which were injuring the patient's health), chrysophanic acid, tar ointment, turpentine, etc.—with only slight benefit, I was induced to try an ointment composed of vaseline, oxide of zinc, and sanitas oil, and was rewarded by a speedy removal of most of the patches of psoriasis, the usual brown discoloration of the skin, and a few small irritable spots alone remaining, which are disappearing under the same treatment, now continued for a month.

I suppose the *modus operandi* is similar to turpentine and like preparations, but sanitas oil has one very great advantage over other applications, and that is its cleanness and freedom from disagreeable odor, and the fact that the linen of the patient is not stained or injured, which is a great consideration in private practice. Of course it is impossible to judge of the value of sanitas without extended trial, which I am unable to give at present, but I shall be very pleased if any member of the profession will give this drug a trial, and make known the result of treatment by this means.

Believe me, Sir, yours, etc.,

R. H. PATERSON, M.R.C.S., etc.

Gainsborough, June 24th, 1883.

OATMEAL v. RICKETS.

To the Editor of THE LANCET.

SIR—Dr. Drewitt attributes rickets to the use of meal. Whilst heartily agreeing with the substance of his article as to the great value of condensed milk in the artificial dieting of children, I cannot but dissent from his views on the influence of meal, which, when properly prepared, I consider to be a most valuable food. Needless to say, this, like any other food when badly prepared and administered, may be incapable of maintaining health or life; but in such cases the symptoms are not those of rickets, but of simple marasmus, characterized by clean tongue, absence of fever, great craving for food, emaciation, and exhaustion. The period when children suffer from meal diet is in early infancy (first to eighth month). Rickets is most frequent after the twelfth month, and in very few cases, in my experience, is meal an element of their diet. Women in this part of the world need no caution against the use of meal. They apparently regard it as unfit for human food, being entirely ignorant how to cook it either for themselves or their children. There is abundant

clinical proof that, properly prepared, meal is in many cases digestible from the earliest days of infancy; that it is capable of maintaining a child in robust health; that many children are reared on it with little or no milk; and that in many cases where cow's milk is rejected in every stage of dilution, the addition of a little well-cooked meal renders it perfectly digestible.

Finally, I do not believe that meal is ever directly concerned in the production of rickets, but that it is an important agent for the relief of that condition.

I am, Sir, yours truly,
ED. GEO. WHITTLE, M.D. Lond.,
Senior Surgeon to the Royal Alexandra Hospital
for Children.

Dyke-road, Brighton, June 26th, 1883.

"LAWN TENNIS LEG."

To the Editor of THE LANCET.

SIR—Some cases of rupture of the pronator group of muscles having been recorded as due to the back stroke in lawn tennis, and termed "lawn tennis arm," I have thought it of sufficient interest to forward you a report of a case that has recently occurred in my practice, where rupture of the plantaris tendon took place during recreation at the same game. It is of more than passing interest, inasmuch as both the tendons gave way on separate occasions, and because no extreme tension can be said to have happened either time.

I was summoned to see J. C. C., aged forty-one, an able-bodied, muscular, healthy Englishman, on Feb. 21st, 1883, who was said to have met with an accident while playing tennis in the Drill Hall (the ground at this time of the year being covered by about four feet of snow necessitating playing under cover). He told me that while reaching for a ball (not at all violently) he was seized with a sudden sharp pain in the left calf. It stung so that he turned round and asked who threw the ball at him. He then found he could not stand or bear any weight on that leg. He was lying on a couch when I reached him, and quite free from pain. I found the calf swollen and stiff, with a slight contraction of the gastrocnemius as if to steady the injured tendon. On deep pressure about the lower fourth of the belly of the gastrocnemius I could feel a small boggy swelling, and this pressure caused much pain. I was feeling the fractured tendon through the thick muscular layer which covered it. No doubt the plantaris tendon had snapped. I put the part at rest, and approximated the ends as well as possible by flexing the leg on the thigh and extending the tarsus. In this position, which he maintained during the healing process, no pain was experienced. In about four weeks he began to walk, though a little lame, and in a short time everything seemed as before. I gave him permission to play tennis again before the middle of May, cautioning him to begin quietly, and not to exert himself. This he did, and in a couple of weeks could play as vigorously as ever and as well, and suffered no pain whatever. On May 29th, after playing a whole two hours hard, he was walking across the ground to take the "serve," when he again felt something suddenly snap, and again made precisely the same remark to the bystanders, asking who struck him on the leg. On arriving I found exactly the same condition as before described, but in the other leg. I have him at present under the same treatment (rest), and I may say he is eagerly looking forward to having it united again, so that he may measure bats once more across the grassy sward.

I am, Sir, yours, etc.,
R. W. POWELL, M.D.

Rideau-street, Ottawa, Canada.

IRIDECTOMY.—A correspondent asks the reasons for performing iridectomy in the operation for extraction of cataract. They are patent. First, in whatever way the operation is performed without removal of a portion of the iris, coughing, vomiting, or failure of some part of the wound to unite frequently leads to prolapse of the iris. Iridectomy materially diminishes or entirely abolishes the chance of this very troublesome accident occurring. Secondly, in a large number of cases, however skilfully the operation is executed, a considerable quantity of cortical substance of the lens remains behind the iris. This, swelling, especially in gouty persons, irritates the iris and sets up iritis, or, gradually filling up the area of the pupil causes secondary cataract, with adhesions of the iris to the remains of the capsule and lens. Iridectomy enables the operator to remove the greater part of such residue of the lens, and thus prevents a second operation. Lastly, when the lens is large and the section is a trifle small, the lens in escaping may stretch, tear, and bruise the iris, and again lead to iritis. By iridectomy all chance of this accident is avoided. Those who practice iridectomy know very well that it has troubles of its own. The hemorrhage from the cut vessels is troublesome, and is withal of bad augury, as showing that the vessels are not healthy. The wound of the iris sometimes induces iritis; and prolapse of the cut edges at the corners of the corneal incision, almost as painful and troublesome as complete prolapse, sometimes occurs. We are inclined to think that in spare, healthy subjects, from fifty to sixty-five years of age, with otherwise sound eyes, iridectomy may be dispensed with; but that when from any cause the result of the operation appears doubtful by anticipation, it will be prudent to have recourse to it. Vision is as perfect after it has been done as in cases where it has been omitted.

THE PROPHYLACTIC POWER OF COPPER.—Dr. Burq, whose researches on the prophylactic virtues of copper in cholera are well known, has followed up his investigation of the merits of the drug by a digest of the figures relating to the last epidemic of typhoid fever which occurred in Paris. He shows that the 40,000 men and women employed in working copper would, if the death-rate among them had been, as with the rest of the population, 1·3 per thousand, have lost fifty of their number. As a matter of fact only ten died, and seven of these were very little exposed to swallowing the copper dust, in which, as Dr. Burq believes, the healing virtues of copper reside. Dr. Burq draws from all these facts the conclusion that the organism of workmen exposed to the action of copper undergoes a progressive cupric impregnation opposed to the development of the microbes of infectious diseases. He proposes, moreover, to verify this conclusion by studying the action of salts of copper upon the microbes cultivated by M. Pasteur.

On July 12th the Bill increasing M. Pasteur's pension from 12,000 to 25,000 francs, with reversion to his wife and children, passed the French Chamber without a division. In reply to certain dissentients, M. Paul Bert cited the English grant to Jenner, and scouted with warmth the charge of sordid motives brought against Pasteur.

Clinical Lecture

ON

TETANY.

at University College Hospital,

By W. R. GOWERS, M.D., F.R.C.P.,

Assistant Physician at University College Hospital, and Physi-
cian to the National Hospital for Epilepsy and Paralysis.

GENTLEMEN—I propose to show you to-day an example of a very rare disease—the spasmodic affection which is termed “tetany.” So rare is it, that probably none of you have hitherto seen a well-marked case, at least in an adult. Because a disease is uncommon it is not, therefore, to be disregarded. There are few diseases, however infrequent, which some of you will not meet with in the future. It is necessary for you to be acquainted with the diseases which are rare, as well as familiar with those which are common.

The patient before you is a cook by occupation, single, and forty years of age. There is nothing in her present healthy aspect to suggest that she is the subject of any malady. But it was otherwise, as some of you may remember, when she first came into the out-patient room, about six weeks ago. Her arms and hands were then fixed by spasm in a peculiar manner. The elbow-joints were slightly flexed, the wrist-joints in somewhat greater degree, while the fingers were strongly flexed at the metacarpo-phalangeal joints and extended at the others, the thumb being adducted and pressed against the side of the first finger so strongly that its last phalanx was bent backwards. The spasm was attended by a painful sense of traction in the affected muscles; it could be overcome by force, but the attempt gave much pain, and the hands afterwards at once resumed the same posture. The legs were free from spasm, and she could walk well. She told us that for three months similar attacks of spasm had come on each morning, which passed away in an hour or so. During the day she would be free, but each evening the spasm recurred. In some of the previous attacks the legs also had become stiff. On the day on which she came to the hospital the spasm had continued without remission. Inquiry into her history elicited no symptoms of hysteria, and nothing in the past, save overwork, to which

the affection could be ascribed. The next day the spasm resumed its intermitting type, coming on in the morning and passing away, to recur in the afternoon and evening. Since then the attacks have gradually become slighter and briefer, and there is now only a little stiffness of the hands for half an hour after rising in the morning. From the first, when the hands were free from spasm, this could be readily induced by pressure on the position of the nerves of the arm. I will show you this effect. The right hand, you observe, is now quite free from spasm. I press firmly on the nerves just below the brachial plexus. At first no change is seen; but now, about a minute having elapsed, you may notice a slight quivering of the abductor indicis, and then the index-finger becomes slowly flexed at the metacarpo-phalangeal joint; the thumb is gradually pressed against it, and next the other fingers are flexed in the same manner; last of all, the wrist also becomes flexed. The pressure being discontinued, the spasm lasts for a few minutes and then passes off. If I compress in the same way the nerves of the left arm, the spasm is induced in like manner in the left hand. No such effect is produced in health by similar compression. There has been much discussion whether the result is due to the compression of the nerves or of the brachial artery which runs beside them. But that it is due to compression of the nerves is proved by the fact that in this patient I can produce it by pressing on the ulnar nerve, away from the brachial artery. A morbid irritability of the nerves is also conclusively shown by the effect of percussion of the nerves. If I give a smart tap to the nerves of the arm, it causes a single quick contraction of the muscles. This is still distinct, although less than it was a few weeks ago, as the patient is recovering, and it was then even more conspicuous in the facial than in the brachial nerves. The slightest tap on the facial nerve in front of the auditory meatus caused an instant momentary contraction in all the facial muscles, exactly similar in character to that produced by the stimulation of a healthy nerve by a single induction shock. The increased irritability of the nerves was as great to electrical as to mechanical stimulation. It was equally marked to faradism and voltaism. The voltaic current, for instance, from a single Coxeter cell, caused contraction in the muscles supplied by the nerve. There was also a qualitative change in the mode of reaction. In health, as you know, if the strength of the current is slowly increased, the first con-

traction is obtained when the negative pole (kathode) is on the nerve and the circuit is closed, or, in the usual terminology, the K.C.C. (kathodal closure contraction) is the earliest, and a stronger current is required to cause contraction when the positive electrode is on the nerve and the circuit is closed or opened (A.C.C., A.O.C.); while a still stronger current is necessary to cause contraction when the negative pole is on the nerve and the circuit is opened (K.O.C.). In this patient, however, the earliest reaction (with one cell) was the positive opening contraction (A.O.C.), and two cells caused not only positive and negative closure contraction, but also distinct tetanic contraction the whole time the current was passing.

Such, gentlemen, are the main points in the case. As the disease is rare, it may be well briefly to mention the chief facts regarding its causation and clinical features. The general history of the disease has been ably sketched by Trousseau,¹ Riegel,² and Weiss,³ abroad; and in this country by Buzzard⁴ and Abercrombie.⁵ The conclusions of these observers I have endeavored to verify and extend by an examination of the details of 150 cases, eight of which have come under my own observation, and the others have been recorded by various writers.⁶ I need not trouble you with statistical results, except as regards age and sex. On other points I will merely give you the chief conclusions which a comparison of these cases suggests.

Tetany is rather more frequent in males than in females, the ratio being as 7 to 6; but this relation, as we shall see, does not obtain at all ages. The disease occurs at all periods of life, from infancy to old age, but is most frequent in early childhood and in early adult life, as is shown by the following table of the cases in which the age is mentioned:—

Age.	Males.	Females.	Total.
1—4	26	8	34
5—9	5	3	8
—	—	—	—
1—9	31	11	42
10—19	23	13	36
20—29	9	15	24
30—39	4	19	23
40—49	5	8	13
50—61	4	0	4
—	—	—	—
	76	66	142

Thus the disease is most frequent in infancy and in the second decade of life. More than half the cases occur during the first twenty years. During early childhood the disease is far more frequent in males than in females (as 3 to 1). Between the ages of twenty and fifty, however, the liability of the sexes is reversed, and females suffer twice as frequently as males. Over fifty, on the other hand, the affection is practically confined to males. A neuropathic heredity can rarely be traced; but that a family tendency to the disease may exist is shown by some facts recorded by Abercrombie.

who, in an interesting description of the disease as it occurs in children,⁷ has mentioned one family in which three cases occurred, and two others in each of which four children suffered.

A direct exciting cause can be traced in about three-fourths of the cases, and the absence of such cause renders the case I have shown you somewhat exceptional. The most frequent excitant is diarrhoea, long-continued and exhausting. Next in frequency are exposure to cold (especially when conjoined with fatigue), acute disease, and lactation. A series of cases in women who were suckling led Trousseau to propose for the disease the name of "nurse's contracture;" but this cause, as he afterwards found, is not so frequent as to justify the designation. Tetany may also come on during pregnancy, usually in the second half, and after delivery. The relative frequency of the disease in adult women is due almost entirely to these various influences of maternity. Other occasional causes are simple anemia, prolonged muscular efforts, alcoholism, and sexual excess, especially masturbation. I have once seen it as a consequence of lead poisoning. In young children it is usually associated with rickets, and is evidently closely allied to the "carpopedal contractions," which are so common in that disease. Laryngismus stridulus and convulsions are frequent accompaniments. In three recorded instances the affection was apparently due to tapeworm, and ceased when this was expelled. Traumatic causes are extremely rare, and yet, strange to say, one surgical operation, excision of an enlarged thyroid, has been followed by an attack of characteristic tetany in four instances.⁸ Although an association with hysteria has been occasionally observed, it is certainly infrequent and exceptional. The acute diseases during or after which tetany has been observed, are (in the order of frequency) typhoid fever, small-pox, cholera, rheumatic fever, measles, febricula, catarrh, and pneumonia. In some epidemics of typhoid fever it has been comparatively frequent, coming on in the latter period of the disease or during convalescence. Lastly, singular epidemics of tetany have been met with, and in some of these hysteria has probably played a larger part than it does in the sporadic cases. In a girl's school in France, in 1876, thirty cases occurred. A still more singular epidemic occurred in certain Belgian prisons in 1846.

The symptoms of the disease, in a moderate degree of severity, are well exemplified in the case I have shown you, and I need not redescribe them. The peculiar posture of the hands during the attacks of spasm is that almost invariably observed, but in a few recorded cases the fingers have been flexed at all joints and the fist thus closed. Still more rarely the wrist and fingers have been extended. In cases of slight and moderate degree the spasm is confined to the hands and forearms, but in the more severe form the lower limbs are also involved. The feet are extended at the ankle-joint, and are inverted in the position of talipes equinovarus. The toes are strongly flexed. The knees are usually extended, rarely flexed. In cases of still greater severity the muscles of the trunk and head participate in the spasm. In the trunk the abdominal muscles, the flexors, suffer more than the extensors of the spine. The thorax may be fixed by the spasm, and even the diaphragm may be involved. Hence respiration is interfered with to the degree of causing cyanosis, and even loss of consciousness. The sterno-mastoids may be rigid, and the head bent forwards. Not un-

⁸ Weiss.

frequently the jaws are closed by spasm in the masseters. The angle of the mouth may be drawn outwards, and the eyes are half shut by contraction in the facial muscles. Movement is interfered with by the spasm, and in proportion to it. There is no paralysis.

Slight contracture may be painless. When considerable, there is usually an unpleasant sense of traction in the affected muscles, sometimes amounting to cramp-like pain, and sharp pains dart up the limb, often taking the course of the nerves. Tingling in the extremities may precede or accompany the attacks of spasm, and sometimes persist in the intervals, accompanied, very rarely, by an actual loss of sensibility to touch, or pain, or both.

The spasm is usually, as in this case, paroxysmal. The attacks are separated by intervals of perfect freedom. The duration of each attack may be a few minutes, hours, or rarely one or two days. The intervals between the paroxysms may be a few hours or a day or two. As a rule, the briefer the paroxysms the more frequently do they recur. Sometimes a slighter degree of spasm continues during the intervals, usually in the arms, rarely in the legs. In other cases, again, in both children and adults, the spasm may continue, scarcely varying in degree, for several days. Thus we may distinguish intermitting, remitting, and continuous forms. But cases are met with which present all gradations between these varieties.

The remarkable alteration in the irritability of the motor nerves has been already mentioned in the description of the case before you. In some cases, as Erb first showed, it is carried to a still higher degree. Not only, as in this patient, is the anodal opening contraction most readily produced, and continuous "tetanic" contraction attends the passage of the current, but a similar tetanic contraction may be induced by the anodal opening stimulation—that is to say, when the positive electrode is placed on the nerve, and the current is broken, so that the current ceases to pass, a prolonged contraction results. This phenomenon is of peculiar interest, since in no other condition has the "anodal opening tetanus" been observed in man. The change in nerve-irritability usually persists a week or two longer than attacks of spasm, but this rule is not invariable. In this patient, for instance, although the spasm still continues in the arms in a slight degree, the irritability of the nerves is becoming normal; the earliest contraction is no longer produced, as it was a few weeks ago, by the anodal opening, but, as in health, by the kathodal closure stimulation.

When the paroxysms are very severe there may be copious perspiration, and sometimes local vasomotor disturbance, redness, and even slight oedema in the affected parts. The pulse is quickened, and, in some cases, a rise of temperature (even to 101° F.) has been observed. But in cases of moderate severity, and also in continuous tetany, these phenomena are absent. The urine, as a rule, is normal, but transient albuminuria has been twice observed,⁹ and once glycosuria coincided with the attacks.¹⁰

The paroxysmal form of tetany may be either slight or severe, but the continuous form never presents a very intense degree. In young children tetany is usually continuous, but the intermitting form is not unknown. In older children and adults it is rare for the spasm to be continuous for several days; as a rule it is intermitting, or there are considerable remissions in its degree. Continuous tetany may persist while the patient

is asleep; in the intermitting form attacks occasionally, although not frequently, come on during sleep. The total duration of the disease varies much. Either the continuous or the intermitting form may last for a few days only. But it is not uncommon for the intermitting form to last for several months. In the patient before you the affection has already lasted for more than four months, and it will probably be another month before she is well. But it is rare for the continuous form, in which the spasm goes on without interruption or considerable remission for several days, to last for more than a few weeks, in adults at any rate. In the majority of cases in which the spasm continues for more than three days, the patient has only one attack; in only a few cases have there been two attacks, and the total duration of the disease has never exceeded a month. The disease is prone to occur either under the influence of an obvious excitant, or sometimes without any appreciable cause. A woman, for instance, suffered from it while suckling each of five children;¹¹ another patient had an attack in each of ten successive winters.¹² In some instances several years have intervened between the attacks—three, six, and even eleven.¹³

Almost all cases end in recovery. Death, when it has occurred, has usually been due, not to the tetany, but to its cause, as diarrhoea. In a very few instances the spasm has caused death, either directly by exhaustion from its violence (as in a case recorded by Trousseau), or indirectly by the influence on the lungs of the repeated interference with respiration, which has induced pulmonary congestion and a low form of pneumonia. Nor does it, as a rule, leave behind any troublesome sequela. In a few cases weakness of the leg was persisted for a time. It has once been immediately followed by chorea,¹⁴ and once by acute and general muscular atrophy.¹⁵

The little that is known of the pathological anatomy of the disease throws no light upon its nature. In a few cases minute changes have been found in the spinal cord,¹⁶ capillary hæmorrhages, accumulations of lymphoid cells around the blood-vessels, and minute foci of myelitis. These are, doubtless, of secondary origin, the result of the acute disturbance of function, and afford no indication of the morbid influence by which the function is disturbed. The one almost solitary fact which we have to guide us in seeking for the seat of the disease is the change in the irritability of the motor nerves. This proves beyond a doubt that the nutrition of these nerves is changed. But such a change in the nerves suggests a similar change in the motor nerve cells of the spinal cord. Of these the motor-axis cylinders are the processes, and share the changes in nutrition of the parent cell. Moreover, the spasm itself indicates that there is a morbid state of grey matter, since we know that only nerve cells can liberate the energy which causes spasm. We may feel sure, therefore, that the motor nerve cells of the cord and the fibres proceeding from them are in a morbid state. The tingling and impaired sensibility occasionally observed, suggest that the sensory cells of the cord may participate in the alteration. But here we must stop. Whether the morbid condition arises primarily in the cord, or descends from higher centres, we cannot tell, and opinions which have

been put forward, that this or that part of the brain is the seat of the disease, are still in the region of unsupported theory. In passing, however, I may direct your attention to the peculiar position which the hand almost invariably assumes during the contracture, a position determined by the predominant spasm in the interossei and some of the lumbricales. It is the opposite posture to the flexion of the phalanges at all joints, in which the "fist is closed." The posture is evidently one of high physiological importance. It enters, in greater or less degree, into many delicate movements of the hands, as in writing; whereas the flexion of the phalanges at all joints occurs especially in coarse movements of the limb, as in lifting a weight. Evidently the "interosseal flexion," as it may be termed, depends upon well-organized nervous arrangements; but where these are placed we do not know, and hence we are ignorant of its localizing significance. It is conspicuous in many cases of post-hemiplegic mobile spasm, an approximation to it is observed in paralysis agitans, and it is the most common posture of the hands during epileptic fits. Probably it ultimately depends on nervous arrangements situated in the cerebral cortex; but doubtless, if so, there are corresponding subsidiary arrangements in the lower centres, even in the spinal cord, through and by means of which it is effected. Hence this posture does not, in itself, justify us in going for the seat of the disease beyond the spinal axis (including the grey matter of the pons and medulla), in which, as we have already seen, a morbid state is indicated by other symptoms.

Of the nature of the change in the nerves and their centres we know almost nothing. The enduring alteration in function, demonstrated by the change in mechanical and electrical irritability, conclusively proves some change in their nutrition, but the fact that this change remains limited to increased irritability, and in the end passes away entirely, proves that it is comparatively slight in degree and probably limited to such fine molecular changes as could not be recognized by any means of investigation at present at our disposal. "Vaso-motor spasm" in the nerve centres has been invoked as an explanation of the attacks of contracture, but it seems to me without sufficient reason. There is nothing in the symptoms to suggest the hypothesis; the adequacy of the mechanism is as unproved as it is improbable; and it leaves unexplained the one fact of the functional alteration in the motor nerves, which is at present the only pathological indication we possess. But functional excitement in the nervous system often induces vaso-motor disturbance, both central and peripheral. The vaso-motor symptoms which have been, in rare cases, observed at the periphery, were clearly secondary in time, and we are justified in assuming that the same is true of the slight and variable traces of similar disturbances in the spinal cord (leucocytal aggregation about the vessels) which have been discovered in one or two severe cases.

In chronic poisoning by ergot there is often contracture which singularly resembles that of tetany, and the similarity has struck many observers,¹⁷ and has suggested the dependence of the disease we are now considering on some toxic influence. But the significance of etiological facts is on the whole opposed to such an assumption. Although in some cases reflex irritation has appeared to excite the disease, it is doubtful whether this plays a large part in its pathology.

The diagnosis of a case of tetany rarely presents any considerable difficulty. The symptoms are char-

acteristic, and in the paroxysmal form are unique. In spite of the unfortunate resemblance in name, it could be confounded with tetanus only in cases in which the spasm develops suddenly with extreme violence, and such cases are so rare that only one or two have ever been recorded. It is sufficiently distinguished in ordinary cases by the peculiar posture of the hands, by the invariable commencement of the spasm in the extremities, and by the fact that the masseters, which generally are the first to suffer in tetanus, are always the last to be involved in tetany. In organic cerebral disease, attended with contracture, this is usually unilateral, and continues not only for a day or two, but for months; there is paralysis as well as spasm; and cerebral symptoms are never absent. Hysterical contracture may resemble tetany in form, but is almost always unilateral. In ergotism the spasm is secondary to other symptoms, and the disease is fortunately scarcely ever met with in this country.

Only under two conditions is the prognosis other than favorable. If the paroxysms are extremely violent, and interfere distinctly with respiration, the disease may be fatal from pulmonary complications. Secondly, if the tetany is due to grave debilitating disease there is considerable danger to life from this cause; but the prognosis in such a case depends on the primary disease, rather than on the secondary malady. The duration of the affection is often difficult to foretell. It will probably be brief if the disease depends on a cause which is speedily removable. It is likely to be long if there is a distinct alteration in the irritability of the motor nerves. If in an adult, the individual attacks continue for several days, the disease is not likely to last more than two or three weeks.

The treatment must first be directed to the removal of any derangement to which the disease is apparently due. Diarrhoea must be arrested; lactation stopped. If the affection followed exposure to cold, and the case is seen early, warm baths and free diaphoresis should be employed. The treatment of the developed malady itself consists in the diminution or arrest of the attacks by sedatives, and in the removal of the morbid state on which they depend by tonics. For the former purpose bromide of potassium is the most effective, but it must be given in full doses, as half a drachm three times a day. Chloral, Indian hemp, and hypodermic injections of morphia have also been found effective, but, as a rule, the bromide answers best. The inhalation of chloroform at first increases the spasm, but all contracture disappears when the patient is fully under its influence, although the subsequent recurrence of the spasm is not thereby prevented. Stimulating liniments to the extremities and ice to the spine have also been observed to lessen the spasm. The voltaic current has been said to do good in some cases, but in others it has so distinctly failed that it is doubtful whether the improvement ascribed to its influence may not have been due to other causes. Those of you who have not read Trousseau's striking lecture on the disease will be startled to learn that the chief treatment for the malady in France twenty years ago was venesection, and what is still more surprising, it is said to have been followed by rapid recovery, even in weakly women. But it was not invariably successful, and where it failed tonics often succeeded.

The most useful tonics are, as might be expected, iron, quinine, and strychnine. In very slight cases no other treatment is needed. The patient you have seen is taking only tincture of nux vomica, and, as you have heard, she is steadily getting well, the disappearance of the augmented irritabil-

¹⁷ Imbert-Goubeyre (1844), Hasse, Moxon, Eulenberg.

ity being a satisfactory proof of the reality of her progress. The continuous tetany of young children is less amenable to sedatives than the paroxysmal variety of adults; and the most important element in its treatment is that of the rickety diathesis which accompanies it, and on which it certainly to a large extent depends.

Clinical Remarks

ON

SOFTENING OF THE CRUS CEREBRI AND PONS, AND ON SYPHILITIC DISEASE OF THE CEREBRAL ARTERIES.

Delivered at St. Thomas's Hospital,

By J. SYER BRISTOWE, M.D., F.R.S.,

Senior Physician to the Hospital.

GENTLEMEN—The four cases to which I wish to call attention present, each of them, individual points of interest; but doubtless their chief value resides in the fact that they have a close pathological and clinical relationship. They are all of them cases of softening of the pons Varolii, or crus cerebri, and adjacent parts. The symptoms were in all cases those of what is roughly termed cross paralysis, and in every instance the affection was ushered in by premonitory symptoms. The symptoms, however, presented considerable differences of detail, and there were differences as regards etiology.

The first case is that of a young man who had contracted a chancre exactly six months before his death, and who was suffering from secondary symptoms in the form of psoriasis at the time when his fatal illness seized him. The symptoms of this illness began five or six weeks before he died (and certainly therefore within five months of his syphilitic inoculation) with occipital headache and sickness. After three or four weeks, or, more exactly, fourteen days before his death, he began to ramble a little in his mind and to be troublesome; and the next morning it was noticed that his pupils were contracted, his conjunctivæ congested, and his left eyelid a little dropped. Five days later, when he woke in the morning, he was found to be hemiplegic on the left side; and after another four days it was noticed not only that the left eyelid was a little dropped, but that there was paralysis of all the muscles of the right eye, excepting probably the superior oblique. Meanwhile the patient was becoming more and more drowsy and stupid, and he died quietly on the fourth day after the paralysis of the muscles of the right eye had declared itself. Syphilitic disease of the internal organs generally arises as a part of the so-called "tertiary symptoms" of syphilis, and therefore late in the progress of the disease, and often after many years have elapsed. Still, as the patient here appeared to have been in all other respects a healthy man, it was assumed during life that his cerebral affection was syphilitic, and he was treated accordingly. Further, it was not difficult to speculate, from the symptoms, as to whereabouts the cerebral lesion would be found. The left-sided hemiplegia pointed to involvement of the motor tract, issuing from the right hemisphere of the brain; and that the part directly implicated was the right crus cerebri or the contiguous portion of the pons had been foreshadowed by the slight ptosis observed in the left upper eyelid. This surmise was confirmed when, a few days subsequently to the occurrence

of hemiplegia, total paralysis of the right third nerve was added to the other phenomena. At the post-mortem examination there was found syphilitic thickening, with obstruction, of the right posterior cerebral artery, and consequent softening, with more or less disintegration in patches, of the right crus cerebri, and of some of the neighboring parts to which this artery is distributed. The paralysis of the right sixth was no doubt due to the thickening of the membranes observed at the base of the brain, and the very partial affection of the left third was probably connected with some special but concurrent lesion of that nerve. It may be assumed, that the patient's early and comparatively vague cerebral symptoms were due to the disease of the arterial walls and slight associated inflammation of the membranes in the neighborhood; that the hemiplegia took place when the channel of the posterior cerebral became suddenly occluded; and that the right third nerve got involved as the area of softening extended.
